PREFACE

General description of the research programme on sustainable Landuse.

The research programme is based on the document "elaboration of the VF research programme in Costa Rica" prepared by the Working Group Costa Rica (WCR) in 1990. The document can be summarized as follows:

To develop a methodology to analyze ecologically sustainable and economically feasible land use, three hierarchical levels of analysis can be distinguished.

1. The Land Use System (LUS) analyses the relations between soil type and crops as well as technology and yield.
2. The Farm System (FS) analyses the decisions made at the farm household regarding the generation of income and on farm activities.
3. The Regional System (RS) analyses the agroecological and socio-economic boundary conditions and the incentives presented by development oriented activities.

Ecological aspects of the analysis comprise comparison of the effects of different crops and production techniques on the soil as ecological resource. For this comparison the chemical and physical qualities of the soil are examined as well as the pollution by agrochemicals. Evaluation of the groundwater condition is included in the ecological approach. Criteria for sustainability have a relative character. The question of what is in time a more sustainable land use will be answered on the three different levels for three major soil groups and nine important land use types.

Combinations of crops and soils

| | Maiz | Yuca | Platano | Piña | Palmito | Pasto | Forestal I II III |
|----------|------|------|---------|------|---------|-------|----------------------|
| Soil I | x | x | x | | x | x | x |
| Soil II | | | | | | x | x |
| Soil III | x | | | x | x | x | x |

As landuse is realized in the socio-economic context of the farm or region, feasibility criteria at corresponding levels are to be taken in consideration. MGP models on farm scale and regional scale are developed to evaluate the different ecological criteria in economical terms or visa-versa.

Different scenarios will be tested in close cooperation with the counter parts.

The Atlantic Zone Programme (CATIE-AUW-MAG) is the result of an agreement for technical cooperation between the Centro Agronómico Tropical de Investigación y Enseñanza (CATIE), the Agricultural University Wageningen (AUW). The Netherlands and the Ministerio de Agricultura y Ganadería (MAG) of Costa Rica. The Programme, that was started in April 1986, has a long-term objective multidisciplinary research aimed at rational use of the natural resources in the Atlantic Zone of Costa Rica with emphasis on the small landowner.

SUMMARY

The Atlantic Zone of Costa Rica is dotted by small red coloured hills which consists of deeply weathered sediments. The deposits are probably of Pleistocene age and are the remnants of a Pleistocene landscape which was eroded by rivers during the last glacial period. A C-14 dating pointed out that one of them (Rio Sucio Profile, location see figure 4.1.) is older than 50,000 years.

Research was done in order to make a geological interpretation of the so-called "Redhill" - deposits and to study their weathering. The geochemical and mineralogical weathering studied was done in order to answer the following questions:

- What geochemical and mineralogical changes are taking place during weathering of these deposits;
- How do different types of sediment influence the weathering processes and the mineralogy and geochemistry of the deposits.

1. Introduction

The Atlantic Zone of Costa Rica is dotted by small red coloured hills which consists of deeply weathered sediments. The deposits are probably of Pleistocene age and are the remnants of a Pleistocene landscape which was eroded by rivers during the last glacial period. A C-14 dating pointed out that one of them (Rio Sucio Profile, location see figure 4.1.) is older than 50,000 years.

The deposits probably consist of fluvial and pyroclastic sediments. The parent material is supposed to be of andesitic composition since it is derived from the volcanic hinterland with mainly andestic volcanism.

The sediment are strongly weathered due to high annual rainfall (about 4000 mm), relatively high temperature (yearly average of 25°C) and their easy weatherability.

Research was done in order to make a geological interpretation of the so-called "Redhill" - deposits and to study their weathering. The geochemical and mineralogical weathering studied was done in order to answer the following questions:

- What geochemical and mineralogical changes are taking place during weathering of these deposits;
- How do different types of sediment influence the weathering processes and the mineralogy and geochemistry of the deposits.

2. Theory.

2.1. Weathering of andesitic material under humid tropical conditions

Weathering of andesitic volcanic material under humid tropical conditions is characterized by rapid degradation (by hydrolysis, oxidation and destruction of primary mineral structures (Colman, 1982)) of the primary minerals, mainly feldspars, pyroxenes and volcanic glass. Dissolution reactions can be written as follows:

The protons used for the reaction can be supplied by dissolved CO_2 in the soil solution.

Due to the usually strong leaching conditions in the humid tropics the liberated base-ions will almost completely be washed out. The Fe^{2+} which come into solution is first oxidized to Fe^{3+} and can precipitate as Fe(hydr)oxides, for instance the poorly ordered mineral ferrihydrite¹⁾.

The liberated Al^{3+} and part of the silica commonly precipitate in secondary minerals, for instance halloysite²⁾ and allophane.

Allophane can be defined as a group of short-range ordered clay minerals that contain silica, alumina and water in chemical combination (Parfitt and Childs, 1988), and has usually a Al/Si-ratio between 1 and 2. Generally, allophane forms from glass (at pH(H₂O) 5 to 7) and feldspar and/of biotite (at pH(H₂O) about 5) in soils with udic moisture regimes and with good drainage. Under these conditions silicic acid and hydroxy-aluminium cations react to give allophane. A pH > 4.7 is required for allophane to precipitate (Parfitt and Kimble, 1989). The formation of allophane can be (partly) prevented by the presence of humus, which can complex the liberated Al^{3+} (Mizota and van Reeuwijk, 1989).

Allophane seems to be formed by rapid weathering of Al- and Si-rich minerals, which results in relatively high concentrations of Al^{3+} and silica in the soil solution. The high concentrations probably cause a rapid precipitation of amorphous and poorly ordered hydrous alumino-silicates, mainly allophane. The exact mechanism of allophane formation has not been found in the literature.

With time allophane may be transformed to halloysite, kaolinite³⁾ or gibbsite⁴⁾ as well as 2:1 type clay minerals depending on the silica concentration of the soil solution (Wright, 1964). Halloysite may probably also be transformed to kaolinite, gibbsite or 2:1 clay minerals. Under humid conditions ferrihydrite can be transformed into goethite⁵⁾. See figure 2.1. for the stability relationships among some minerals in the system $\text{K}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2-\text{H}_2\text{O}$ at 25°C.

figure 2.1.: Stability relationships among some minerals in the system K₂O-Al₂O₃-SiO₂-H₂O at 25°C (After Drever, 1988).

- 1) ferrihydrite = approximately: Fe₂O₃.2FeOOH.2*6H₂O
- 2) halloysite = Al₄[Si₄O₁₀/OH)₂]*4H₂O
- 3) kaolinite = Al₄[Si₄O₁₀/OH)₂]
- 4) gibbsite = Al(OH)₃
- 5) goethite = Fe(OOH)

2.2. Dissolution rate.

An important process in weathering is dissolution of the primary minerals. Three processes can control the rate of dissolution of an inorganic solid phase (figure 2.2., after Drever, 1988):

1) Reaction at the surface of a mineral grain (reaction control), typically detachment of species at the mineral surface. When surface reaction is rate controlling, the concentrations of the solutes immediately adjacent to the grain will be the same as in the bulk solution.

2) Transport (normally by diffusion) of ions or molecules in solution to or from the grain surface (diffusion or transport control). In this case, the solution immediately adjacent to the solid will be more or less in equilibrium with the solid, and concentration gradients will exist in solution.

3) Diffusion of ions or molecules through a layer of solid reaction products or a layer of partly altered primary mineral surrounding the solid. For many purposes this can be regarded as a type of surface reaction control; it will result in a uniform solution composition.

Mixed kinetics (partly diffusion controlled, partly reaction controlled) may also occur, but generally either diffusion or

reaction is the dominant control, and the other can be neglected.
(after Drever, 1988).

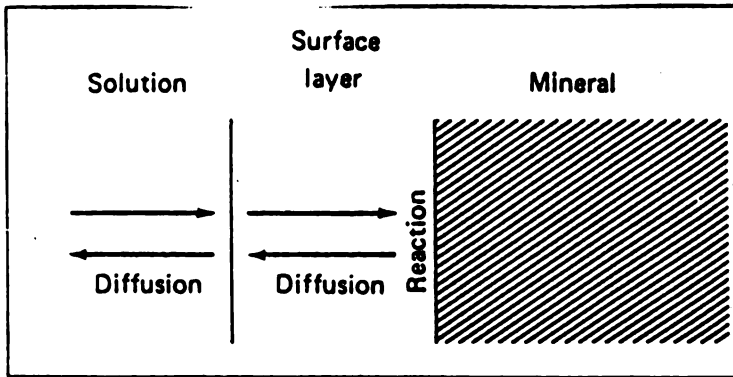

Figure 2.2: Schematic drawing of a mineral reacting with solution. The rate determining step may be reaction at the surface of the mineral, diffusion through a solid layer at the grain surface, or diffusion in solution.

3. Methods.

3.1. Field descriptions.

In order to describe the 'Redhill'-deposits four geographically separated locations, three roadcuts and a canalcut, were selected. At each location a profile of about 6 meters deep was chosen for detailed description. For these descriptions the profiles were divided into several layer-types, mainly on a textural and geological basis, varying in thickness between between 5 and 200cm. The most important soil-characteristics and the geology of each layer were described. Depending their texture and deposition mechanism (according to the field descriptions) the layers were grouped into five classes, the strongly altered topsoil fell into class 0.

3.2. Sampling procedures.

All layers of the four profiles were sampled by taking representative field moist mixed samples (each about 500 g) from the centre of the layers. If the layer was thicker than 100cm two samples were taken, one in the upper part and one in the lower part. In total about 50 samples were collected.

3.3. Analytical procedures.

Texture was determined after destruction of organic matter in the field moist sample with H_2O_2 , and dispersion using a mixture of sodium polymetaphosphate and NH_3 . Clay and silt (2 - 53 micrometer) contents were measured by the hydrometer method (Gee and Bauder, 1986). After the measurement, the suspensions with clay and silt were discarded, and the remaining samples were dried and passed over a nest of sieves, in order to determine weight percentages of the fractions $>2mm$, $2mm-500\mu m$, $500-212\mu m$ and $212-53\mu m$. Clay dispersion of weathered volcanic material is often difficult. Texture analysis are probably relatively reliable since much attention was paid to the dispersion of the sample.

The bulk chemical composition (major elements and selected trace elements) was determined by X-ray fluorescence. After ignition at $900^\circ C$ to determine contents of crystalline water plus organic matter, glass tablets were obtained by melting the samples with 2.4 lithium tetraborate and analysed on a Philips XRF assembly. Major oxide components were normalized to 100%. FeO is measured as Fe_2O_3 .

Mineralogy of the clay fraction, collected after texture analysis, was determined by X-ray diffraction, after saturation of the clay minerals with Mg^{2+} . The samples were scanned in wet condition and after drying at 25° and $100^\circ C$.

Acid ammonium oxalate extractable iron and aluminium (Fe_{ox} and Al_{ox}) were determined by shaking a 1 g soil air dry /100 ml reagent solution for 4 h in the dark (Blackmore et al., 1987) and measuring Fe and Al by AAS.

3.4. Weathering indices.

Weathering indices were calculated in order to study changes in geochemistry due to weathering processes. The weathering potential index (WPI) and the product index (PI) (after Reiche, 1950) were used:

$$\text{WPI} = 100 * \Sigma \text{Bases} / (\Sigma \text{Bases} + \text{SiO}_2 + \Sigma \text{R}_2\text{O}_3)$$

$$\text{PI} = 100 * \text{SiO}_2 / (\text{SiO}_2 + \Sigma \text{R}_2\text{O}_3)$$

For the calculation of the indices the molair fractions of the elements were used. MgO, CaO, K₂O and Na₂o were grouped as total bases; Al₂O₃, TiO₂ and Fe₂O₃ were grouped as R₂O₃.

The WPI is a measure for the amount of base-ions in the sample. The WPI of an average andesite is about 18.3. The WPI rapidly decreases if bases are lost.

The PI is a measure for the amount of Si in the samples. The PI of an average andesite is about 78.9. If silica is lost the PI decreases.

R₂O₃ functions as a reference constituent, since it is supposed to be the least mobile component in the soil.

Fresh sediment samples from the Río Chirripo (by van Seeters, 1992) function as an indicator for the chemical composition of the primary sediments of the 'Redhill'-deposits.

4. Site descriptions

The locations of the four profiles is shown in figure 4.1.

4.1. Río Frío Uno profile:

The profile consists of a sequence of sandy and silty to clayey deposits, which are probably of fluvial origin. The texture of the individual layers and the alteration of fine and coarse textured layers would suggest that they are floodplain sediments. The sandy layers could be crevasse splays, while the silty and clayey layers could represent more finely grained floodplain accumulations.

It was not possible to determine the parent material of the upper two meters of the profile because of strong alteration by weathering processes and homogenisation by soil fauna. No buried soils were found which suggests that there was no appreciable weathering during deposition of the sediments.

4.2. Río Frío Dos profile:

The profile consists mainly of coarse sandy deposits with pebble-rich layers, probably of fluvial origin. Their coarse texture and crossbedding structures suggests that the deposits are in-channel sediments of a river.

It was not possible to determine the parent material of the upper 150 cm of the profile because of alteration by weathering processes and homogenisation by soil fauna. No buried soils were found which suggests that there was no appreciable weathering during deposition of the sediments.

4.3. Río Sucio profile:

The profile consists of a sequence of sandy and silty to clayey deposits, probably fluvial. The texture of the individual layers and the alteration of fine and coarse textured layers would suggest that they are floodplain sediments, consisting of sandy crevasse splays and probably small streambeds, and fine grained floodplain accumulations. The lowest fine grained layer in the profile contains much organic matter and may represent a backswamp environment.

It was not possible to determine the parent material of the upper 130 cm of the profile because of alteration by weathering processes and homogenisation by soil fauna. No buried soils were found which suggests that there was no appreciable weathering during deposition of the sediments.

4.4. Neguev profile:

The profile consists of different types of sediments; sandy, pebble-rich and silty to clayey deposits and two very poorly sorted layers with a clayey to coarse texture containing pebbles. The two poorly sorted layers are probably lahars. On top of these layers lies a silty to clayey sediment which could be pyroclastic deposit or a fluvial floodplain accumulation.

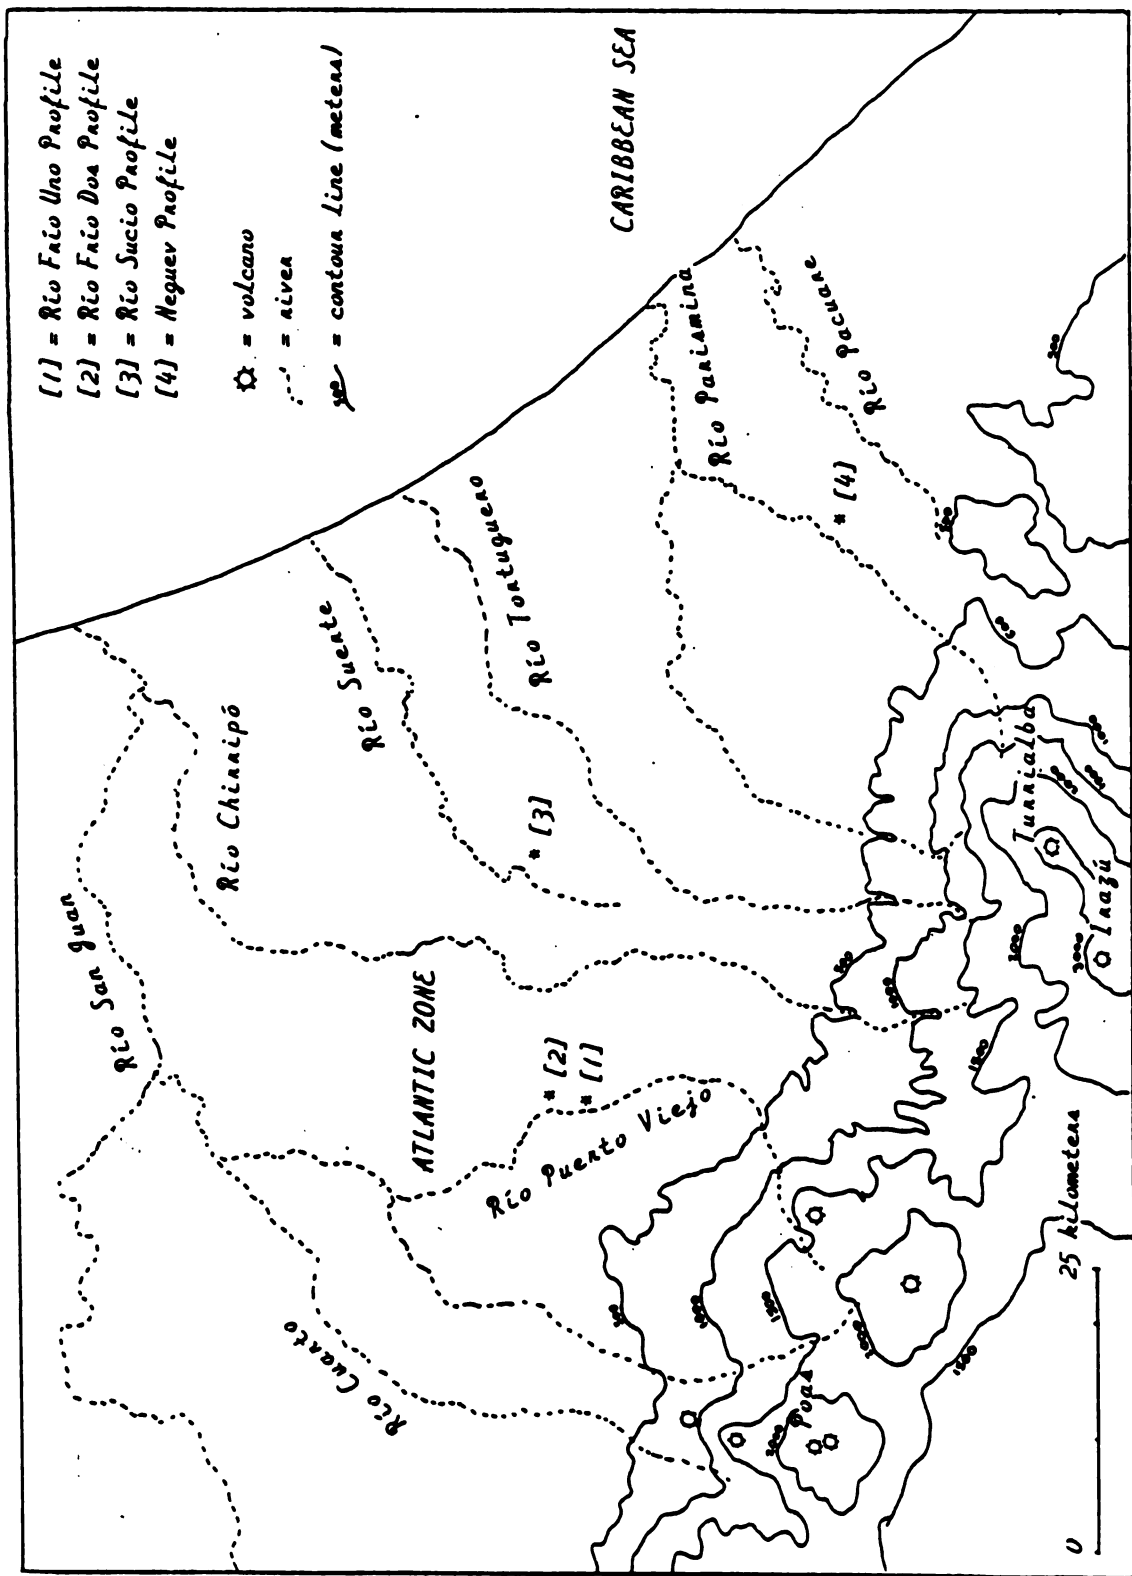

figure 4.1: Locations of the four sampled profiles.

5. Results

5.1. Texture and mineralogy.

| K | 600 | 1 | 36 | 2.0 | 0.45 | 0.19 | 0 | 1 |

Table 5.1.: Mineralogy of the clay fraction and clay content of Río Frio Uno Profile.

Clay-, Al_{ox}- and Fe_{ox}-content in mass fraction %.

Gibb. = Gibbsite, Crist. = Cristobalite; Content in sample: 3= much, 2=intermediate, 1=little, 0=nil, '-'= not analysed.

Aratio = 1.0nm clay minerals/ 0.7nm clay minerals.

The clay content decreases with depth from 58% in the top soil to 6% for layer-type 2 at 575 cm depth and 36% for layer-type 1 at 600 cm depth. The clay content of layer-type 1 is higher than that of layer-type 2 (figure 5.1.).

The crystalline clay fraction mainly consists of 1.0nm-halloysite and 0.7nm-halloysite or kaolinite, gibbsite and cristobalite. Little goethite and quartz is present. In the topsoil some 2:1 clay minerals were detected.

The Aratio (which is the ratio between the peak height of the 1.0 nm clay and the 0.7nm clay in the X-ray-diffractograms) increases with depth for layer-type 0 and 2 from 0.8 to 8.5. The ratio of layer-type 1 seems to decrease with depth from 3 to 2.

The amount of gibbsite decreases with depth. In layer-type 0, the topsoil, most gibbsite occurs. Layer-type 2 contains more gibbsite than layer-type 1.

The amount of cristobalite increases with depth, the content of layer-type 2 is higher than that of layer-type 1.

Al_{ox}-content is relatively low throughout the profile, between 0.30 and 0.45 %.

CLAY vs. DEPTH
Río Frío Uno Profile

figure 5.1: Clay content versus depth, Río Frío Uno Profile.

5.1.2. Río Frío Dos profile:

| Sample | Depth cm | Layer- type | Clay | Aratio | Al _{ox} | Fe _{ox} | Gibb. | Crist. |
|--------|-------------|----------------|------|--------|------------------|------------------|-------|--------|
| A1 | 50 | 0 | 53 | 0.6 | 0.44 | 0.37 | 3 | 1 |
| A2 | 125 | 0 | 56 | 3.0 | 0.40 | 0.72 | 3 | 0 |
| B | 195 | 2 | 22 | 2.0 | 0.80 | 0.51 | 3 | 2 |
| C | 270 | 3 | 3 | 3.0 | 4.85 | 0.48 | 1 | 3 |
| D | 315 | 2 | 5 | 0.0 | 4.40 | 0.38 | 0 | 0 |
| E | 335 | 3 | 5 | 0.0 | 5.80 | 0.37 | 1 | 1 |
| F | 380 | 2 | 3 | 0.0 | 3.25 | 0.32 | 0 | 0 |
| G | 425 | 3 | - | - | - | - | - | - |
| H | 430 | 1 | 23 | 10 | 0.22 | 0.40 | 0 | 2 |
| I | 480 | 2 | 5 | - | 2.20 | 0.30 | 0 | 3 |
| J | 550 | 2 | 0 | 2.0 | 3.90 | 0.10 | 0 | 0 |

Table 5.2.: Mineralogy of the clay fraction and clay content of Río Frío Dos Profile.

Clay-, Al_{ox} and Fe_{ox}-content in mass fraction %.

Gibb. = Gibbsite, Crist. = Cristobalite; Content in sample: 3=--much, 2=intermediate, 1=little, 0=nil, '-' = not analysed.

Aratio = 1.0nm clay minerals/ 0.7nm clay minerals.

The clay content decreases with depth from about 55% in the top soil to 0% for layer-type 2 at 550 cm depth. Clay content of layer-type 1 is higher than that of layer-type 2 which is higher than that of layer-type 3.

The crystalline clay fraction mainly consists of 1.0nm-halloysite and 0.7nm-halloysite or kaolinite, gibbsite and cristobalite. Little goethite and quartz is present. In the topsoil few 2:1 clay minerals are detected.

The Aratio (which is the ratio between the peak height of the 1.0 nm clay and the 0.7nm clay in the X-ray-diffractograms) does not seem to be correlated with depth and varies between 0.0 and 3.0 for layer-type 0, 2 and 3 and is 10.0 for layer-type 1 at 430 cm depth. Whenever the ratio is 0.0, the clay fraction does not contain crystalline clay minerals.

The amount of gibbsite decreases rapidly with depth, with layer-type 3 always containing more gibbsite than an underlying layer-type 2.

The distribution of cristobalite increases throughout the profile is very irregular.

Al_{ox}-content is relatively high in coarse textured layers that occur deeper than 250 cm. It varies between 2.20 and 5.80 %. The Al_{ox}-content in layer-type 3 is higher than that in type 2.

5.1.3. Río Sucio profile:

| Sample | Depth cm | Layer- type | Clay | Aratio | Al _{ox} | Fe _{ox} | Gibb. | Crist. |

Table 5.3.: Mineralogy of the clay fraction and clay content of Río Sucio Profile.

Clay-, Al_{ox}- and Fe_{ox}-content in mass fraction %.

Gibb. = Gibbsite, Crist. = Cristobalite; Content in sample: 3= much, 2=intermediate, 1=little, 0=nil, '--' = not analysed.

Aratio = 1.0nm clay minerals/ 0.7nm clay minerals.

Clay content decreases with depth from 76% in the top soil to 4% for layer-type 2 at 615 cm depth and 13% for layer-type 1 at 660 cm depth. Clay content of layer-type 1 is higher than that of layer-type 2 (see figure 5.2.).

The crystalline clay fraction mainly consists of 1.0nm-halloysite and 0.7nm-halloysite or kaolinite, gibbsite and cristobalite. little goethite and quartz is present.

The Aratio increases with depth from 1.4 in the top soil to about 18.3 at 660 cm depth. One very high value of 32.0 occurs at 500 cm depth. The Aratio for layer-type 1 does not differ systematically from that of layer-type 2.

The amount of gibbsite decreases with depth and is relatively low. The amount of cristobalite does not seem to vary systematically with depth.

Al_{ox}-content is relatively low throughout the profile, less than 0.52 %, except for sample C which contains 1.75 %.

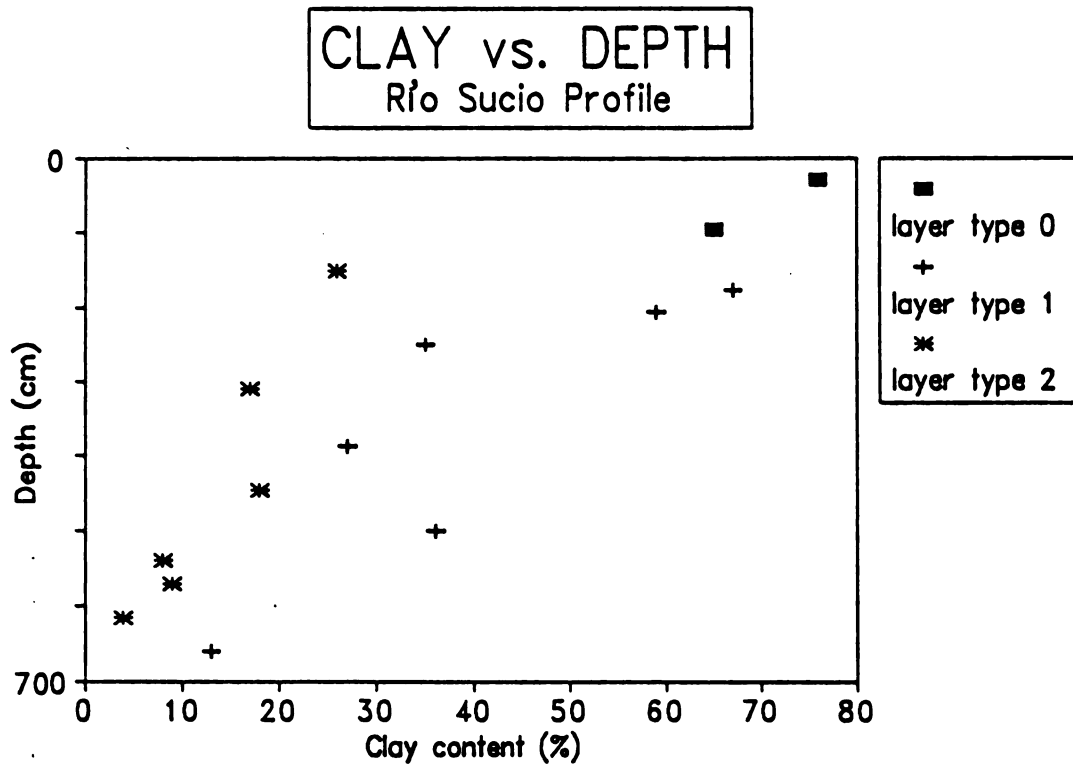

figure 5.2: Clay content versus depth, Río Sucio Profile.

5.1.4. Neguev profile:

| Sample | Depth cm | Layer- type | Clay | Aratio | Al _{ox} | Fe _{ox} | Gibb. | Crist. |

Table 5.4.: Mineralogy of the clay fraction and clay content of Neguev Profile.

Clay-, Al_{ox}- and Fe_{ox}-content in mass fraction %.

Gibb. = Gibbsite, Crist. = Cristobalite; Content in sample: 3= much, 2=intermediate, 1=little, 0=nil, '-' = not analysed.

Aratio = 1.0nm clay minerals/ 0.7nm clay minerals.

The clay content decreases with depth from 49% in the top soil to about 10% at 650 cm depth. Sample J contains relatively much clay. Clay content of layer-type 3 and 4 seems to be lower than that of layer-type 1 and 2.

The crystalline clay fraction mainly consists of 1.0nm-halloysite and 0.7nm-halloysite or kaolinite, gibbsite and cristobalite. Little goethite and quartz is present.

The Aratio increases with depth from 1.0 in the topsoil to 24.0 for layer-type 3 at 635 cm depth and 15.0 for layer-type 2 at 655 cm depth.

The amount of gibbsite rapidly decreases with depth.

The amount of cristobalite increases with depth and is higher for layer-types 2, 3 and 4 than for layer-type 1.

Al_{ox}-content is relatively high, higher than 1.0 % for five samples. Samples C and D have very high values, 19.70 and 7.30 %.

5.2. Chemistry.

5.2.1. Río Frio Uno profile:

| Sample | Depth cm | Layer- type | ΣR_2O_3 | SiO_2 | $\Sigma Bases$ | WPI | PI |

| Fresh sediment: | | 1 | | | | 11.8 | 78.9 |
| | | 2 | | | | 18.1 | 81.1 |

Table 5.5.: Analyse results of profile Río Sucio.
 ΣR_2O_3 , SiO_2 and $\Sigma Bases$ in molair fraction %.
 Fresh sediment data from van Seeters, 1992.

The samples consists for the major part of the oxides of the elements Al, Fe and Si. In the topsoil the ΣR_2O_3 content is about 45 % ($Al_2O_3 = 35$ %, $Fe_2O_3 = 9$ % and $TiO_2 = 1$ %) and it decreases to about 25 % ($Al_2O_3 = 20$ %, $Fe_2O_3 = 5$ % and $TiO_2 = 0.6$ %) at 550 cm depth. SiO_2 content increases from about 55 % in the top soil to 70 % at greater depth. Throughout the profile the base-ion content is very low, lower than 1.5 %.

The WPI increases with depth from 0.50 in the topsoil to 0.96 for layer-type 2 and 1.36 for layer-type 1. The WPI of layer-type 1 is higher than that of type 2 (see figure 5.3.).

The PI first decreases from 57.2 in the top soil to 51.4 in the first layer-type 2 layer beneath the top soil at 245 cm depth, and then increases to 71.6 at 600 cm depth. The PI of layer-type 1 is higher than that of type 2 (see figure 5.4.).

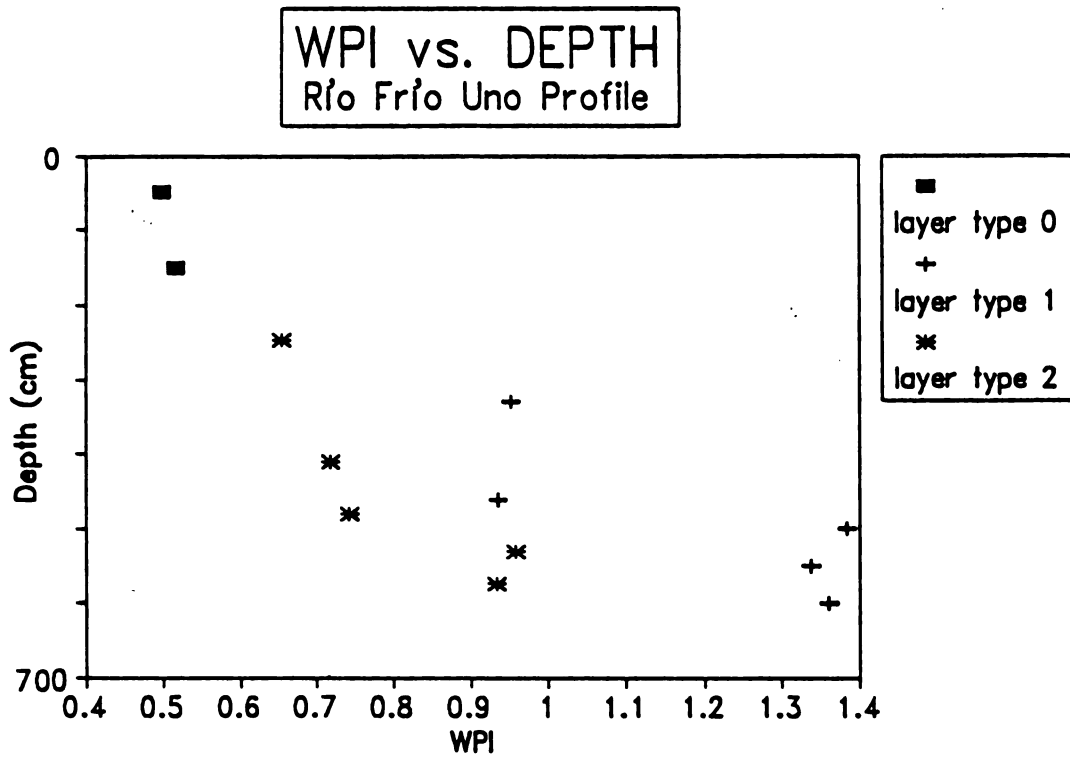

figure 5.3: WPI versus depth, Río Frío Uno Profile.

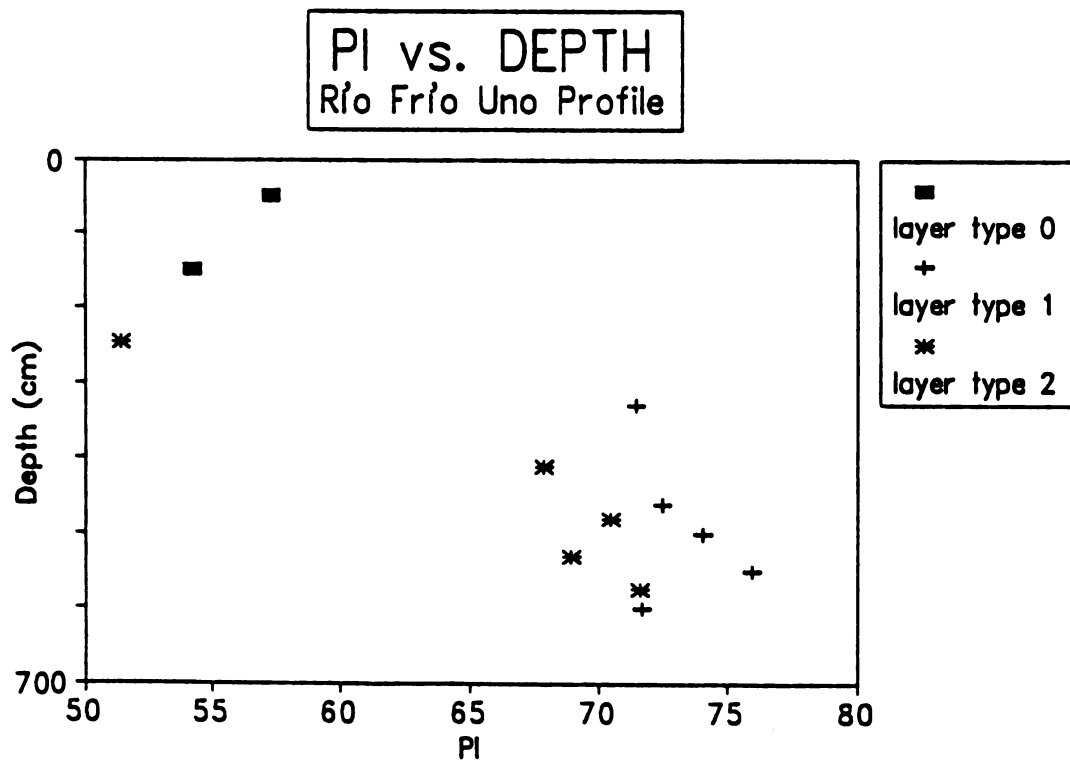

figure 5.4: PI versus depth, Río Frío Uno Profile.

5.2.2. Río Frio Dos profile:

| Fresh sediment: | | 1 | | | | 11.8 | 78.9 |
| | | 2 | | | | 18.1 | 81.1 |

Table 5.6.: Analyse results of profile Río Sucio.

ΣR_2O_3 , SiO_2 and $\Sigma Bases$ in molair fraction %.

Fresh sediment data from van Seeters, 1992.

The samples consists for the major part of the oxides of the elements Al, Fe, Si and at a greater depth than 200 cm also of the base-cations. In the topsoil the ΣR_2O_3 content is about 50 % (Al_2O_3 = 37 %, Fe_2O_3 = 12 % and TiO_2 = 1%) and it decreases to about 21 % (Al_2O_3 = 16 %, Fe_2O_3 = 5 % and TiO_2 = 0.5%) at 550 cm depth. SiO_2 content increases from about 48 % in the top soil to 68 % at greater depth. Content of base-cations is in the upper two meters of the profile very low, beneath this depth it is very high and varies between 1.3 and 16.8 % (at 550 cm). $\Sigma Bases$ is mainly determined by the quantity of MgO.

The WPI strongly increases with depth from about 0.5 in the top soil to 16.8 at 550 cm depth. The WPI of layer-type 2 seems to be higher than that of type 3 (see figure 5.5.).

The PI first decreases with depth from 52.8 in the topsoil to 44.8 in the first layer-type 2 layer beneath the topsoil at 195 cm, then it rapidly increases to 74.5 for layer-type 2 at 550 cm depth. The index seems to be higher for layer-type 2 than for that of 3 (see figure 5.6.).

Table 5.7.: Analyse results of profile Río Sucio.
 ΣR_2O_3 , SiO_2 and $\Sigma Bases$ in molair fraction %.
 Fresh sediment data from van Seeters, 1992.

The samples consists for the major part of the oxides of the elements Al, Fe and Si. In the topsoil the ΣR_2O_3 content is about 35 % ($Al_2O_3 = 26$ %, $Fe_2O_3 = 8$ % and $TiO_2 = 1$ %) and it varies throughout the profile between 32 and 38 %, except for the high value just beneath the topsoil. SiO_2 content varies between 60 and 68 %, except for a low value for again the layer just beneath the top soil. Throughout the profile the base-ion content is very low, generally lower than 1.5 %.

The WPI first seems to decrease with depth from 1.0 in the top soil to about 0.3 at 350 cm depth, except for the high value at 150 cm depth. Then the WPI increases to about 0.8 for layer-type 1. The index of layer-type 1 seems to be slightly higher than that of layer-type 2 (see figure 5.7.).

The PI slightly increases with depth from 64.1 in the top soil to about 65.0 for layer-type 1 at 660 cm depth, except for the layer-type 2 layer just beneath the top soil which has a low value of 50.1. The PI of layer-type 1 is higher than that of layer-type 2 (see figure 5.8.).

Table 5.8.: Analyse results of profile Río Sucio.
 ΣR_2O_3 , SiO_2 and $\Sigma Bases$ in molair fraction %.
 Fresh sediment data from van Seeters, 1992.

The samples consists for the major part of the oxides of the elements Al, Fe and Si. In the topsoil the ΣR_2O_3 content is about 50 % ($Al_2O_3 = 37$ %, $Fe_2O_3 = 11$ % and $TiO_2 = 1$ %) and it decreases to about 30 % ($Al_2O_3 = 21$ %, $Fe_2O_3 = 8$ % and $TiO_2 = 1$ %) at greater depth, except for a high value just beneath the topsoil and a low value at 610 cm depth. SiO_2 content increases from about 48 % in the top soil to between 55 and 68 % at greater depth, a very low value occurs just beneath the topsoil. Throughout the profile the base-ion content is very low, except for the content between 550 and 650 cm where it is higher than 9 %.

The WPI seems to increase slightly with depth from 0.7 in the top soil to about 1.8 at 655 cm depth, except for three very high values between 550 and 650 cm. The WPI of layer-type 2, 3 and 4 seem to be higher than that of layer-type 1 (see figure 5.9.).

The PI increases with depth from 49.0 in the top soil to about 68 at 425 cm depth, except for the low value for the layer-type 2 layer beneath the top soil. Beneath 425 cm it seems to decrease again to about 65 (see figure 5.10.).

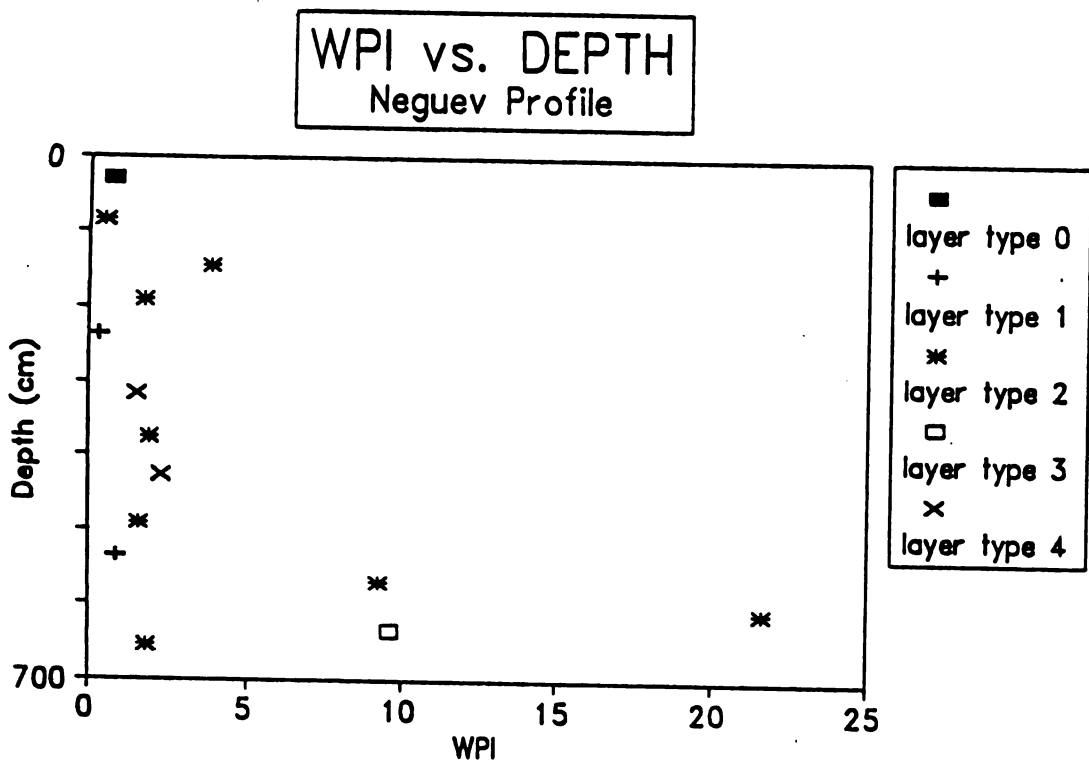

figure 5.9: WPI versus depth, Neguev Profile.

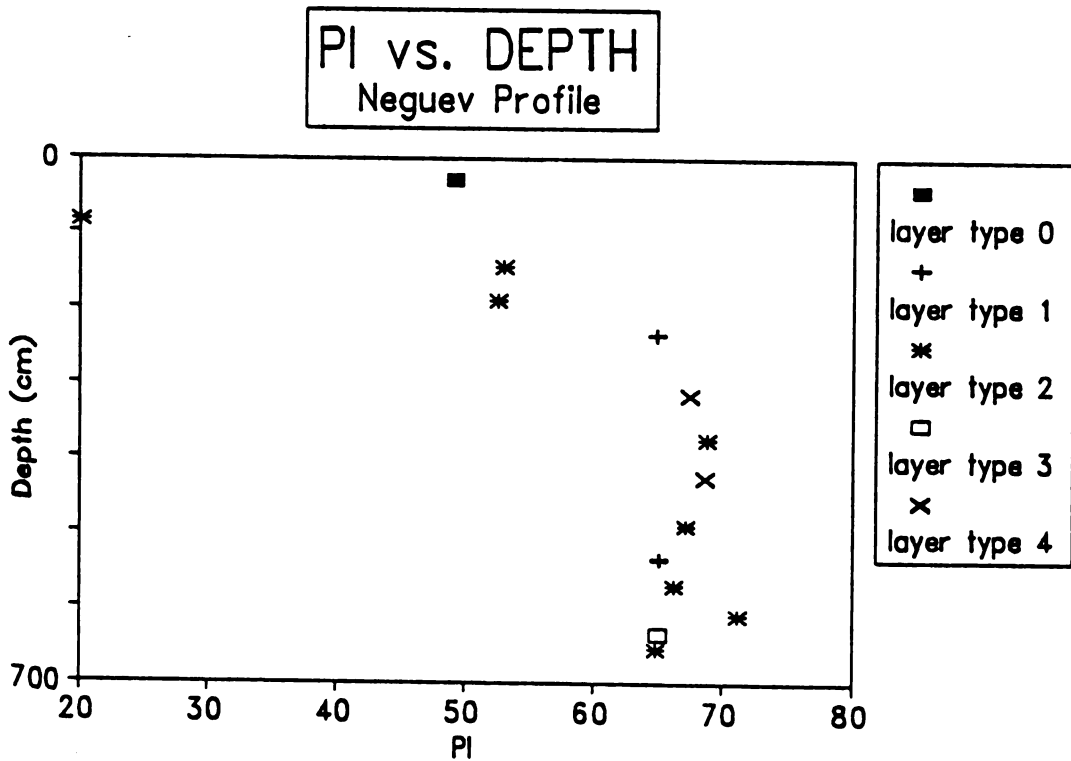

figure 5.10: PI versus depth, Neguev Profile.

6. Discussion

6.1. Influence of layer-depth.

The top soils of the four profiles are strongly weathered and homogenised. It is not possible to determine the parent material. Occurrence of organic matter will probably influence the weathering processes. Therefore the top soils will not be discussed.

The clay fractions of the layers underlying the topsoil, mainly consist of the following minerals: 1.0nm-halloysite, 0.7nm-halloysite or -kaolinite, gibbsite, some amorphous clay minerals and cristobalite. These minerals are supposed to be secondary since they are typically weathering products and they occur in large quantities in the clay fraction. Gibbsite is stable at the relatively low H_4SiO_4 -concentrations (figure 2.1), 0.7nm-halloysite or -kaolinite is likely to be a rekrystallisation product of 1.0nm-halloysite. Cristobalite is stable at relatively high H_4SiO_4 -concentrations.

In all profiles the clay-content, the gibbsite content and the amount of 0.7nm-halloysite or -kaolinite compared to 1.0nm-halloysite (figure 6.1), decrease with depth. Except for some samples of the Río Frío Dos Profile in which the Aratio is 0, this will be discussed in chapter 6.4. The cristobalite-content seems to increase with depth. This indicates that leaching decreases with depth. In the layers just beneath the top soil the silica-concentration is probably lowest and gibbsite can be formed, in the lower part of the profile the silica-concentration is higher so cristobalite can precepsitate. In the upper part of the profile more 0.7nm-clay minerals have formed, probably by recrystallisation of 1.0nm-halloysite.

figure 6.1: Aratio versus depth.

The discussion of the chemical composition will be restricted to the Río Frío Uno and the Río Frío Dos Profile. The composition of the Río Sucio Profile is probably influenced by its low topographical situation and the composition of the sediments of the Negeuv Profile seems to be too heterogenous.

The WPI is a measure for the the base-ion content in the samples. During weathering of the primary minerals the base-ions are rapidly washed out, so the WPI can be seen as an indicator for the amount of unweathered base-ion containing primary material (probably mainly plagioclase, augite, hypersthene and some volcanic glass (Niewenhuyse et al, in prep.)). In all profiles the WPI increases with depth, which suggests that the amount of unweathered material in the upper part is lower than that in the lower part. The PI, which is a measure for the silica-content in the samples, also increases with depth. Silica leaching is probably most advanced in the upper part and decreases with depth.

It can be concluded that the weathering grade of the sediments decreases with depth. In the upper parts of the profiles less primary minerals are left and more silica is leached than in the lower parts.

Factors influencing the weathering rate are: Temperature, the amount of percolating water and the ionic activities in the soil solution. The temperature plays no important role since it probably is almost constant throughout the profiles. If only downward vertical water percolation is considered, the amount of percolating water is probably also nearly constant throughout the profile (annual rainfall is nearly 3000 mm, evapotranspiration can be about 1000 mm a year).

An explanation for the difference in weathering stage with depth could be difference in ion-activities in the soil solution. During the downward percolation, the soil water can take up liberated ions. The higher concentration of solutes in the soil solution at greater depth could cause a lower weathering rate of the sediments at these depths. The concentration of protons can also influence the weathering rate. Just beneath the top soil it is probably higher due to a higher pCO_2 , which can cause a higher weathering rate.

If the concentration of dissolved ions would indeed control the weathering rate of a sediment containing mainly feldspars and pyroxenes, it is probably a diffusion controlled proces. The diffusion of the dissolved ions from the mineral surface would be the rate controlling step. In layers with less water percolation the slower removal of solutes in the soil solution will cause higher ion-activities. This can result in a lower weathering rate of primary minerals in these layers.

If not only vertical water percolation is considered, the differences in weathering stage between the upper and the lower parts of the profiles can also be explained by the occurrence of lateral water movement. Removal of part of the percolating water by a lateral flow, will result in a higher amount of percolating water and a higher weathering rate in the upper parts than in the lower parts. This can be the case in the investigated profiles.

6.2. Influence of layer-type.

In this chapter the discussion will again be limited to the Río Frío Uno and the Río Frío Dos Profiles.

Differences in mineralogy and chemistry between the layer-types seem to exist.

Gibbsite only occurs in the coarse (type 2- and 3-) sediments, with a predominance in the coarsest (type 3-) layers. In the Río Frío Uno Profile the coarser textured layers also contain more cristobalite than the fine textured layers. According to the Aratio, the fine textured sediments in this profile seem to contain more kaolinite than 1.0nm-halloysite. This can be partly a result of determining the Aratio by measuring the peak-height instead of the the peak-surface. The clay minerals in the fine textured layers are probably more poorly cristallized (figure 6.2). High Al_{ox} -values only occur in type 2- and type 3-layers, which will be dicussed later.

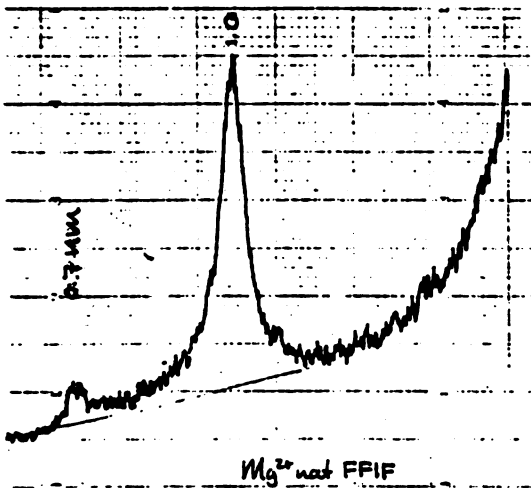

figure 6.2.a

figure 6.2.b

figure 6.2: In coarse textured layer FIF (fig.b) the clay minerals are better cristallised than in the finer textured layer FIG (fig.a).

The WPI (a measure for the base-ion content) and the PI (measure for the silica content) are highest in the finest textured layers and lower in the coarsest textured layers (figure 6.3. and 6.4.). This indicates that fine textured sediments have suffered less base-ion and silica leaching and contain more primary minerals than the coarse textured ones.

It seems reasonable to conclude that weathering stage of the sediments is texture-dependent. When texture becomes coarser, weathering will be more advanced. This cannot be the result of differences in layer-depth since the layer-types occur throughout the whole profiles. Difference in chemical composition during sedimentation is probably also not the cause, since it would be expected that coarse textured fresh sediment contain more base-ions and silica than finer textured sediments. However the low WPI- and PI-value of the fine textured type 1-layer in the Río

Frío Dos Profile can be the result of a different (preweathered) chemical composition of the primary material.

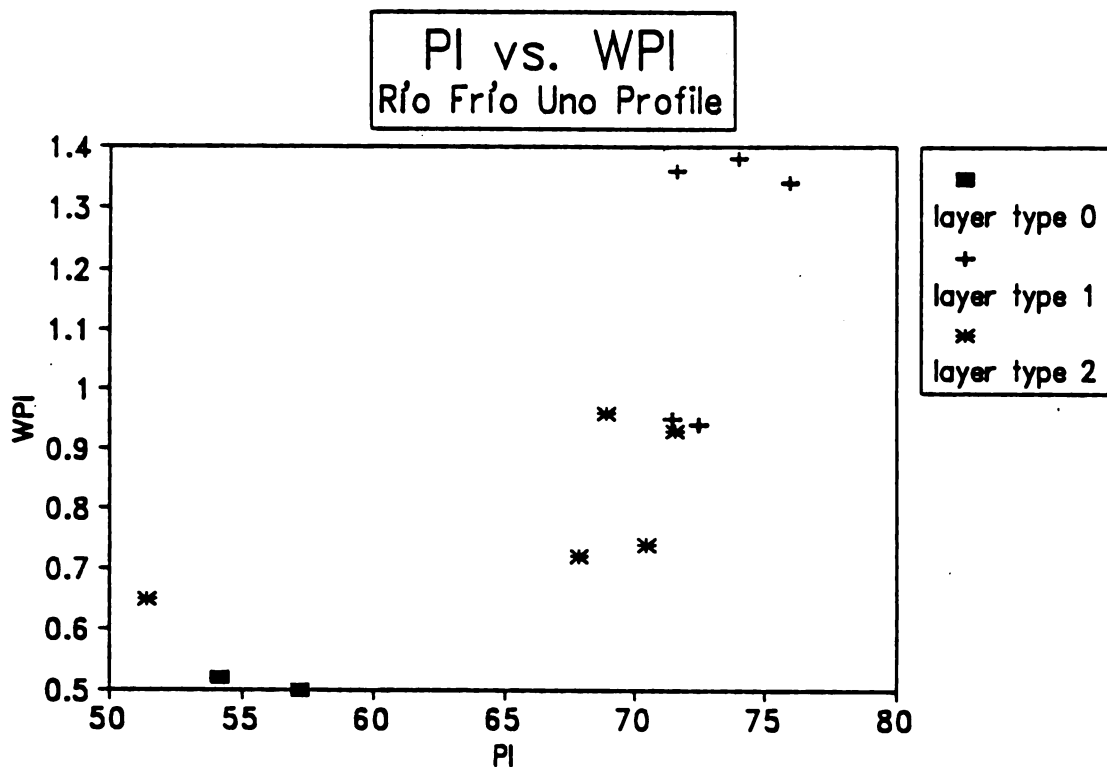

figure 6.3: PI versus WPI, Río Frío Uno Profile.

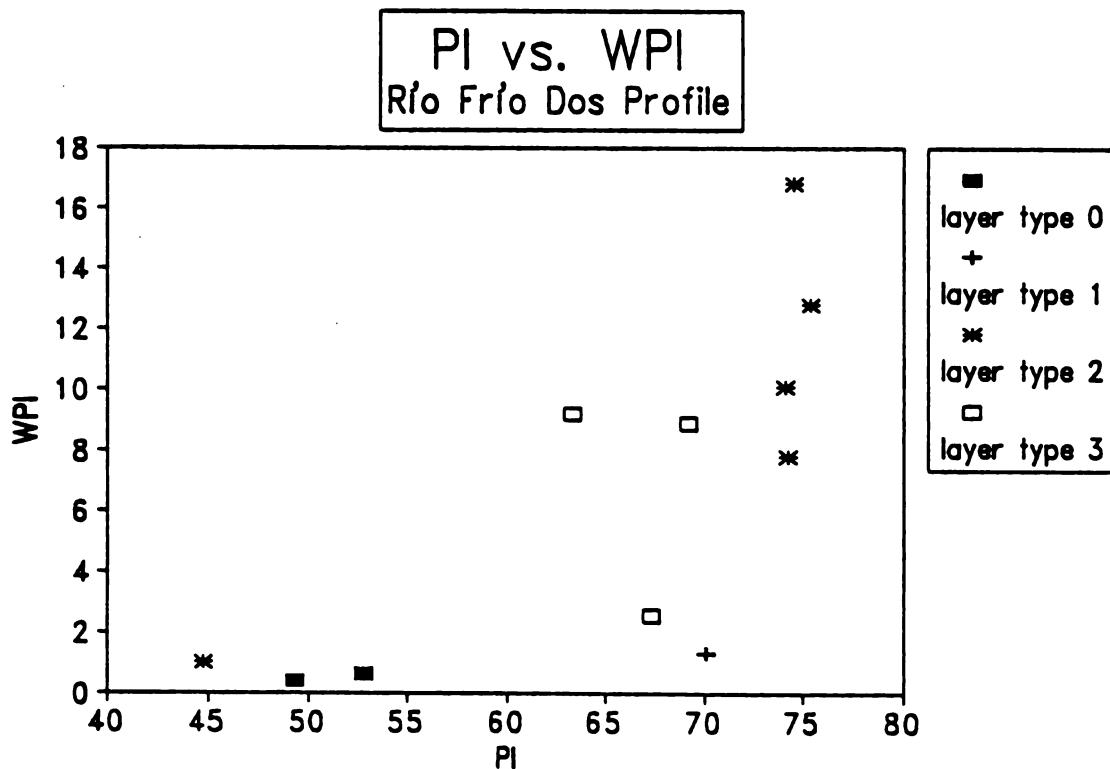

figure 6.4: PI versus WPI, Río Frío Dos Profile.

An explanation for the texture-depending weathering rate can be difference in permeability of the layer-types. Probaly most water will percolate through the coarse texured layers and weathering products will be removed more rapidly than in the finer textured layers. This will result in different ion-activities of the soil solutions. The highest will occur in the finest texuerd layers, the lowest in the coarsest textured layers. If weathering of the sediments is a diffusion controlled proces, the ionic strength of the soil solution will control the weathering rate. It will be highest in the coarsest textured and lowest in the finest textured layers.

This explanation only holds when there actually can be lateral water flow. In both profiles the soil water can mainly follow the coarsest textured sediments. Evidence of stagnating water in the form of reduction mottles in the fine textured layers is found in the Río Frío Uno Profile.

The micro-hydrology in the profiles probably plays an important role in the weathering of the deposits.

The coarser textured sediments in the Río Frío Uno Profile also contain more cristobalite than the finer texured sediments. This is not expected since the coarse textured layers are stronger leached (occurrence gibbsite). The occurrence of critobalite in the coarse textured layers could be the result of seasonal variation. In the drier parts of the year the cirumstances for the forming of cristobalite could be more favourable (less water percolation, higher ion-activities), while in the more humid parts of the year the forming of gibbsite could be predominant.

6.3. Differences between the profiles.

Differences in mineralogy and chemistry between the profiles exist.

Variation in the amount of Al_{ox} in the profiles will be discussed later.

Generally the weathering of the deposits is characterised by rapid removal of the base-ions and a slower removal of silica. Part of the silica will precipitate in secondary products. The oxides of Fe, Al and Ti seem to be the least mobile components in the soil and undergo relative enrichment during weathering. The amount of base-ions between the profiles varies strongly.

The Río Frío Uno Profile, the Río Sucio Profile and the upper 550 cm of the Neguev Profile contain very little primary material comparing to fresh sediments (WPI profiles < 1.5 , WPI fresh sediment = 12-18). The Río Frío Dos Profile (beneath 200 cm) and the lower part of the Neguev contain relatively much primary material (WPI profiles = 8-20). Deposits containing much primary minerals generally have a relatively high Si-content. This indicates that the Río Frío Dos Profile and the lower part of the Neguev Profile seem to be less weathered than the other deposits.

Maybe the Río Frío Dos Profile-deposits are younger, and therefore less weathered. However the top soil is not thinner than that of the Río Frío Uno Profile and both profiles seem to belong to the same formation (distance between them is several hundred meters), so difference in age of the profiles is not likely to be the reason for a different weathering stage.

Another explanation can be differences in hydrology. The previous chapters pointed out that the micro-hydrology plays an important role in the weathering of the 'Red-hill'-deposits. In the Río Frío Uno and the Río Sucio Profile probably more water has percolated which can have resulted in a more advanced weathering. Field observations confirm appreciable difference in weathering stage within a few meters distance. The sample taken from the Río Frío Dos at 550cm depth, was almost fresh, while the same layer a few meters further seemed to be more weathered.

The differences in hydrology can be caused by the topographical situation of the deposits. In some situations lateral water transport in the upper part of the profile can be stimulated. This can result in differences in weathering stage throughout the profile.

The variety in chemical composition of the Neguev Profile-layers can have stemmed partly from differences in primary composition. The type 4-layer, likely to be a lahar, can have contained relatively much preweathered material. The underlying sands were probably relatively unweathered. The lahar, which is a relatively impermeable deposit, can also have prevented part of the soil water from percolating through the underlying sediments. So the the underlying sediments can be less weathered.

Beneath the top soil the Rio Sucio Profile contains relatively little silica. This can be the result of its location on the bottom of a small valley. Probably more water has percolated through the profile which caused a stronger silica-leaching. Probably vertical water percolation was predominant so difference in weathering stage between the layer-types does not seem to exist.

6.4. Occurrence of allophane.

In order to determine the content of allophane-like products in the samples, the Al_{ox} -content was measured, which probably is a measure for the content of Al-humus complexes and allophane-like products. Since the organic matter-content in the layers beneath the top soil is supposed to be nil, the Al_{ox} -content is probably a measure allophane.

In the Río Frío Uno and the Río Sucio Profile allophane is almost absent. Some Río Frío Dos Profile-samples have allophane-contents of 6 %. In these samples the clay fraction is almost completely amorphous (figure 6.5.) and the Aratio is 0. Allophane content increases linearly with the amount of primary material (figure 6.6.). The lower part of the Negev Profile shows the same correlation. However in the upper part some high allophane-contents occur in stronger weathered material.

figure 6.5: Clay fraction is almost amorphous in diffractogram of sample F2D.

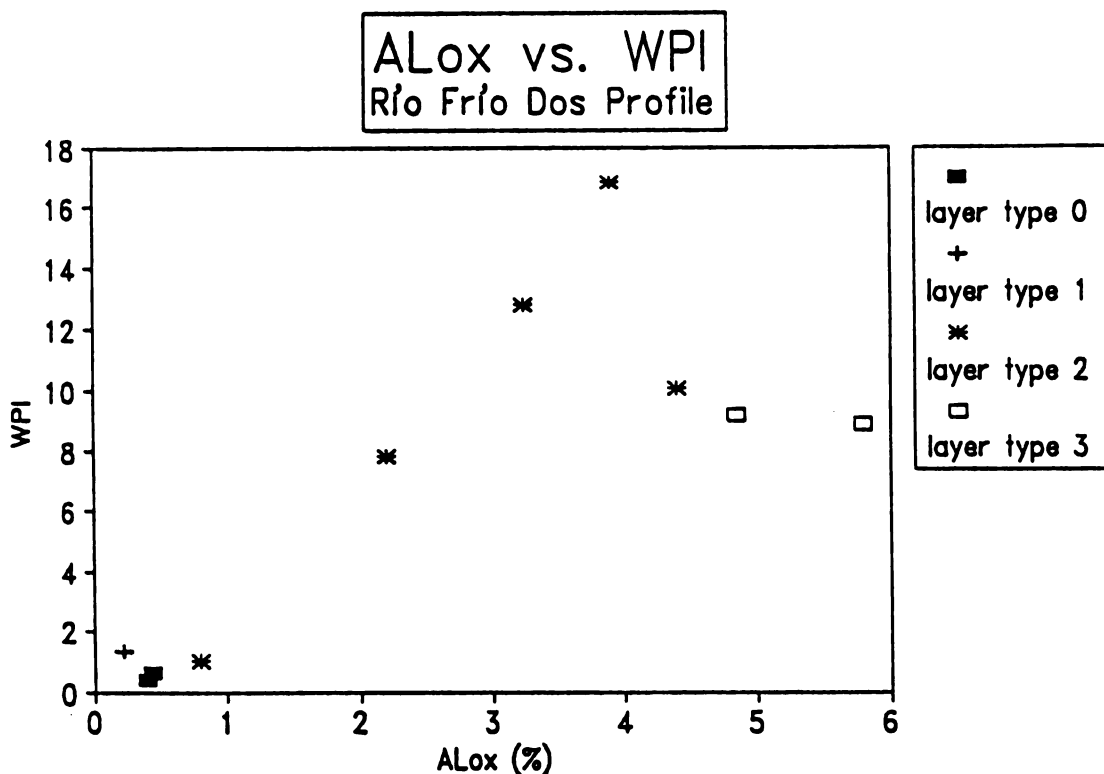

figure 6.6: Al_{ox} versus WPI, Río Frío Dos Profile.

Factors that probably influence the allophane content are (see chapter 2.1): Parent material, pH, presence of humus and the age of the deposits. Humus and pH does probably not play an important role since humus is absent in the layers below the top soil (according to the field descriptions) and the pH in these layers is probably higher than 4.7 (only layers containing much organic matter probably have a pH that is lower than 4.7).

Difference in allophane-content can probably best be explained by the weathering stage of the deposits. Allophane mostly occurs in presence of unweathered material, and is likely to be formed by rapid weathering of primary minerals. In stronger weathered material, the allophane could have been recrystallised to gibbsite, kaolinite or halloysite. The parent material can also have played a role in the forming of allophane, in preweathered sediments, which does not contain enough feldspars and pyroxenes, it is probably never formed. This could be confirmed by the absence of of allophane the the finest textured layers, which have probably contained some preweathered material.

The presence of allophane in the upper part of the Neguev Profile with the absence of primary minerals, could indicate that the formation of allophane has just stopped since the primary minerals are all dissolved.

7. Conclusions

The 'Redhill'-deposits in the Atlantic Zone of Costa Rica consist for the major part of fluvial sediments. As a result of the humid tropical conditions they are deeply weathered.

Weathering is characterised by rapid dissolution of the primary minerals. The liberated base-ions are almost completely washed out (in some cases to depths of at least 600 cm). The silica will partly be washed out and will partly precipitate in secondary minerals. The oxides of Fe, Al and Ti are the least mobile components.

Most important secondary minerals are 1.0nm-halloysite, 0.7nm-halloysite or -kaolinite, gibbsite, cristobalite and some amorphous and poorly ordered clay minerals, for instance allophane.

Weathering seems to be most advanced in the upper part of the deposits and weathering intensity decreases with depth. This can be explained by difference in ionic strength of the soil solution between the upper and lower parts. Higher ion-activities probably slow down the weathering rate. Lateral water transport also seems to play an important role, since it causes differences in the amount of percolating water between the upper and the lower parts of the profiles. The deepest situated layers will receive less percolating water (probably because of lateral removal) and are therefore less weathered.

Weathering rate of the sediments seems to depend partly on texture. Weathering of coarse textured sediments is more advanced than that of fine textured sediments, which can be the result of differences in permeability. Probably most water will percolate through the coarsest textured and therefore most permeable sediments. In the finer textured sediments the water probably stagnates. This causes differences in ionic strengths of the soil solutions. In the coarse textured sediments it will be lowest, which will result in a higher weathering rate of the coarse textured sediments. Weathering rate of the finer textured sediments will be lower.

Differences in weathering stage between the different locations exist. Some deposits contain more primary material and more early stage weathering products (for instance allophane). This can be the result of differences in (micro-) hydrology of the deposits.

Hydrology probably strongly influence the weathering processes. More research should be done in order to determine the (micro-) hydrology of the 'Redhill'-deposits and its influence on the weathering rate.

APPENDIX 1

Analysis data:

XRD:

Typical x-ray diffractograms. After heating at 100°C, the 1.0 nm peak is transformed into a 0.7 nm peak; 1.0 nm halloysite crystallizes into 0.7 nm-halloysite or kaolinite.

Texture analysis and XRD-results:

APPENDIX 2

Field descriptions:

Profile description FF1.

Date: 10/7/91, middle of the rainy season
 Locality: Frank van Ruitenbeek
 Station: Rio Puerto Viejo
 Coordinates: 283000/540000, Rio Sucio
 Access: road cut, 6m deep
 Elevation: 60m
 Altitude:
 Synographic position: top of hill
 Topography: hilly
 Slope: flat
 Vegetation: bush and grassland
 Climate: humid tropics
 Geology: pleistocene alluvial deposits
 Drainage class: well drained
 Moisture conditions of soil: moist
 Depth of groundwater table: > 6m
 Soil outcrops: nil
 Surface stoniness: nil
 Degree of erosion: nil
 Presence of salts/alkali: nil
 Human influence: deforestation

Characteristics: The profile is situated in a 6m deep road cut and built up of fluvial sand-rich and clay-rich layers with red, brown and brown clours.

Horizons:

a) 0-200: Dark yellowish brown (10YR 3/6); clay; friable; weak coarse angular blocky structure; diffuse and smooth boundary to:

b) 200-290: Dark yellowish brown (10YR 3/6); sandy clay loam; firm; brown, thin sesquioxides coatings; very few, strongly weathered, rounded gravel; gradual and smooth boundary to:

c) 290-375: Yellowish red (5YR 4/6); clay; firm; very few small, soft, white concretions; in the upper 4cm frequent, large, hard, black concretions; structureless; abrupt and smooth boundary to:

d) 375-445: Strong brown (7.5YR 4/6); sandy clay; very friable; few white, black and yellow, small and large (<3cm), soft nodules (concretions/mineral fragments?); structureless; abrupt and smooth boundary to:

e) 445-470: Yellowish brown (10YR 5/6); common medium, orange and black mottles (<4cm); clay; firm; abrupt and wavy (containing few, small, grey mottles) to:

f) 470-490: Dark yellowish brown (10YR 4/5); few, small, white mottles; coarse sandy loam; continuous, thick, sesquioxides along the layers; weakly cemented; strongly weathered sand grains; cross lamination; abrupt and smooth boundary to:

g) 490-510: Yellowish brown (10YR 5/6) and strongly brown (7.5YR 3/8); few white and grey mottles; clay; firm; abrupt and wavy to:

h) 510-545: Dark yellowish brown (10YR 4/4); coarse sandy loam; continuous, thick, sesquioxides along the layers; weakly cemented; strongly weathered sand grains; few, rounded, weathered gravel; cross lamination; abrupt and smooth boundary to:

i) 545-560: Yellowish brown (10YR 5/6) and strongly brown (7.5YR 3/8); few fine/medium, distinct (reduction-) mottles; clay; firm; abrupt and smooth boundary to:

j) 560-595: Dark yellowish brown (10YR 4/4); coarse sandy loam; continuous, thin sesquioxides; weakly cemented; 575cm; discontinuous, pisolithic, black/brown pan (<3cm); cross lamination; abrupt and smooth to:

k) 595-610: Yellowish brown (10YR 5/6) and strongly brown (7.5YR 3/8); common fine/medium, irregular grey (reduction-) mottles; sandy, medium, prominent, black mottles (<2mm); clay; firm;

DEPOSITS

Profile FF1:

a) 0-200: Soil

b) 200-290: Poorly sorted; sand with few pebbles; fluvial

c) 290-375: Clay; fluvial;

d) 375-445: Moderately sorted; sand with few pebbles (<3cm); fluvial

e) 445-470: Clay; fluvial;

f) 470-490: Cross bedding; well sorted; medium to coarse sand; fluvial

g) 490-510: Clay; fluvial.

h) 510-545; Cross bedding; moderately sorted; medium to coarse sand with few pebbles; fluvial

i) 545-560: Clay; fluvial;

j) 560-595: Cross bedding; well sorted; medium to coarse sand; few grind lenses; fluvial

k) 595-610: Clay; fluvial;

Profile description PF2

Date/season : 10/7/91, middle of the rainy season
 Author : Frank van Ruitenbeek
 Location : Rio Puerto Viejo
 Coordinates : 200m north of FPI
 Type : road cut, 6m deep
 Elevation : 60m
 Landform :
 Physiography : top of small hill
 Topography : hilly
 Slope : flat
 Vegetation : small bushes and palmito
 Climate : humid tropics
 Geology : pleistocene fluvial deposits
 Drainage class : well drained
 Moisture conditions : moist
 Depth groundwater table : > 6m
 Rock outcrops : nil
 Evidence of erosion : nil
 Presence of salts or alkali : nil
 Human influence : deforestation

Characteristics: 6m deep road cut, situated in a red hill, consisting of relatively coarse fluvial deposits with clearly visible crossbedding.

Horizons:

- a) 0-150: Yellowish brown (10YR 4/4); clay; friable; weak very coarse angular, blocky structure; diffuse and smooth boundary to:
- b) 150-240: Yellowish brown (10YR 3/6); few white mottles; sandy clay; firm; few rounded pebbles (< 3cm); abrupt and wavy boundary to:
- c) 240-300: Dark yellowish brown (10YR 3/6); very poorly sorted, clay to coarse pebbles (< 15cm), partly cemented; rounded pebbles (50%) touch each other; clear, wavy boundary to:
- d) 300-330: Yellowish brown (10YR 5/6); rounded, medium to very coarse sand (< 0.5cm); weakly cemented; cross lamination; abrupt and wavy boundary to:
- e) 330-340: Dark yellowish brown (10YR 4/4); pebble-rich (< 2cm, rounded); weakly cemented with orange yellow sesquioxides; clear and wavy boundary to:
- f) 340-420: Yellowish brown (10YR 5/6); hardly weathered, fine to very coarse sand; few moderately rounded pebbles (< 2cm); coating of sesquioxides along the layers; weakly cemented; few black concretions; cross lamination; abrupt and wavy boundary to:
- g) 420-425: Black, strongly cemented layer, containing pebbles (< 2cm); abrupt and wavy boundary to:
- h) 425-440: Dark yellowish brown (10YR 3/4); loamy clay; firm; few white small concretions; clear and wavy boundary to:
- i) 440-520: Dark yellowish brown (10YR 4/6); fine-coarse sand; partly strongly cemented with sesquioxides; contains few brown clay layers (< 4cm) and gravel, with pebbles to 2cm; cross lamination; gradual and wavy boundary to:
- j) 520-570: Dark yellowish brown (10YR 4/6); hardly weathered, fine to medium sand; partly cemented with sesquioxides; weak cross lamination; contains brown sand (!)(10YR 3/4).

Profile PF2:

- a) 0-150: Soil
- b) 150-240: Moderately sorted; sand with few pebbles (< 3cm); fluvial
- c) 240-300: Poorly sorted; coarse grained with many pebbles (< 15cm); fluvial; stream bedding
- d) 300-330: Cross bedding; moderately sorted; medium to very coarse sand; fluvial
- e) 330-340: Pebbles (< 2cm); fluvial; stream bedding
- f) 340-420: Cross bedding; moderately sorted; fine to coarse sand; fluvial
- g) 420-425: Small pebbles; fluvial; stream bedding
- h) 425-440: Clay; fluvial;
- i) 440-520: Cross bedding; moderately sorted; fine to coarse sand; few clay lenses; fluvial
- j) 520-570: Cross bedding; well sorted; fine to medium sand; fluvial

Profile description PP2

Date/season : 10/7/91, middle of the rainy season
 Author : Frank van Ruitenbeek
 Location : Rio Puerto Viejo
 Coordinates : 200m north of PP1
 Type : road cut, 6m deep
 Elevation : 60m
 Landform :
 Physiography : top of small hill
 Topography : hilly
 Slope : flat
 Vegetation : small bushes and palmito
 Climate : humid tropics
 Biology : pleistocene fluvial deposits
 Drainage class : well drained
 Moisture conditions : moist
 Depth groundwater table : > 6m
 Rock outcrops : nil
 Evidence of erosion : nil
 Presence of salts or alkali : nil
 Human influence : deforestation

Characteristics: 6m deep road cut, situated in a red hill, consisting of relatively coarse fluvial deposits with clearly visible crossbedding.

Horizons:

- a) 0-150: Yellowish brown (10YR 4/4); clay; friable; weak very coarse angular, blocky structure; diffuse and smooth boundary to;
- b) 150-240: Yellowish brown (10YR 3/6); few white mottles; sandy clay; firm; few rounded pebbles (< 3cm); abrupt and wavy boundary to;
- c) 240-300: Dark yellowish brown (10YR 3/6); very poorly sorted, clay to coarse pebbles (< 15cm), partly cemented; rounded pebbles (50%) touch each other; clear, wavy boundary to;
- d) 300-330: Yellowish brown (10YR 3/6); rounded, medium to very coarse sand (< 0.5cm); weakly cemented; cross lamination; abrupt and wavy boundary to;
- e) 330-340: Dark yellowish brown (10YR 4/4); pebble-rich (<2cm, rounded); weakly cemented with orange yellow sesquioxides; clear and wavy boundary to;
- f) 340-420: Yellowish brown (10YR 5/6); hardly weathered, fine to very coarse sand; few moderately rounded pebbles (< 2cm); coating of sesquioxides along the layers; weakly cemented; few black concretions; cross lamination; abrupt and wavy boundary to;
- g) 420-425: Black, strongly cemented layer, containing pebbles (< 2cm); abrupt and wavy boundary to;
- h) 425-440: Dark yellowish brown (10YR 3/4); loamy clay; firm; few white small concretions; clear and wavy boundary to;
- i) 440-520: Dark yellowish brown (10YR 4/6); fine-coarse sand; partly strongly cemented with sesquioxides; contains few brown clay layers (< 4cm) and gravel, with pebbles to 2cm; cross lamination; gradual and wavy boundary to;
- j) 520-570: Dark yellowish brown (10YR 4/6); hardly weathered, fine to medium sand; partly cemented with sesquioxides; weak cross lamination; contains brown sand (!!) (10YR 3/4).

Profile PP2:

- a) 0-150: Soil
- b) 150-240: Moderately sorted; sand with few pebbles (<3cm); fluvial
- c) 240-300: Poorly sorted; coarse grained with many pebbles (<15cm); fluvial; stream bedding
- d) 300-330: Cross bedding; moderately sorted; medium to very coarse sand; fluvial
- e) 330-340: Pebbles (<2cm); fluvial; stream bedding
- f) 340-420: Cross bedding; moderately sorted; fine to coarse sand; fluvial
- g) 420-425: Small pebbles; fluvial; stream bedding
- h) 425-440: Clay; fluvial;
- i) 440-520: Cross bedding; moderately sorted; fine to coarse sand; few clay lenses; fluvial
- j) 520-570: Cross bedding; well sorted; fine to medium sand; fluvial

Location of the Río Frio Uno (FF1) and the Río Frio Dos Profile (FF2) part of the map 'Río Sucio'

Profile description FS3

Date of observation : 17/7/1991, middle of the rainy season
 Observer : Frank van Ruitenbeek
 Location : canal at Rio Suerte
 Coordinates : 267000/560000, Rio Suerte
 Elevation : canal cut, 7m deep
 Station : 50m
 Geomorphology : middle in slope of small hill
 Topography : hilly
 Slope : gently
 Vegetation : grass
 Climate : humid tropics
 Geology : pleistocene fluvial deposits
 Drainage class : well drained
 Moisture conditions : moist
 Groundwater table : 7m
 Outcrops : nil
 Degree of erosion : nil
 Degree of salt or alkali : nil
 Human influence : deforestation

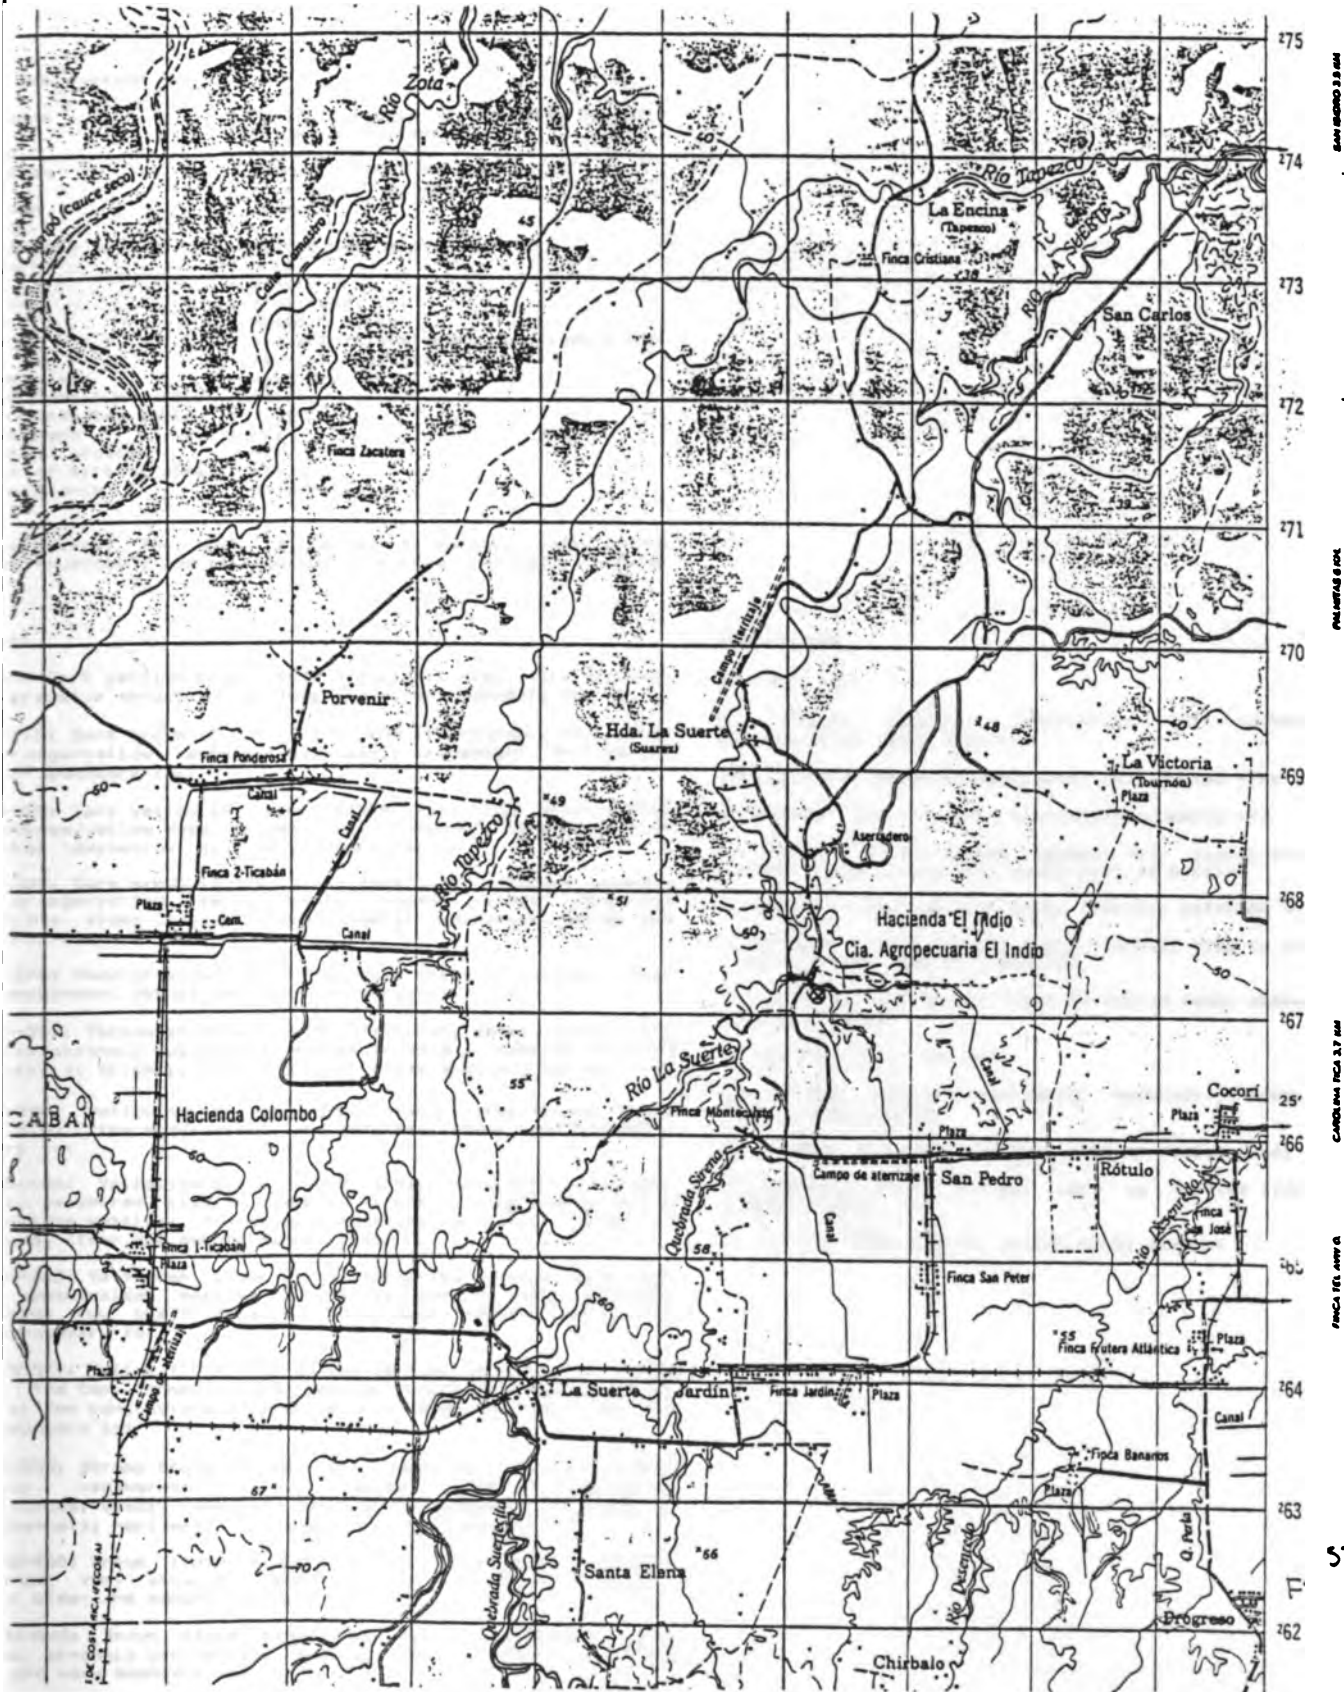

Characteristics: The profile is situated in a 7m deep canal cut
 consisting of strongly weathered fine to coarse grained fluvial
 sediments.

Horizons

0-60: Strong brown (7.5YR 4/6); clay; firm; weak, very coarse
 laminar structure; gradual and smooth boundary to:
 60-130: Dark yellowish brown (10YR 5/4); few orange brown
 mottles (Fe₂O₃); clay; firm; very weak coarse, granular
 structure; clear and smooth boundary to:
 130-170: Dark yellowish brown (10YR 4/4); clay; firm; with
 lens (<10cm thick) of well sorted, weathered, medium/coarse
 sand (black, yellow, red and grey grains); angular, strongly
 sheared, pebbles (<3cm) (green, yellow and red coloured); clear
 smooth boundary to:
 170-185: Yellowish brown (10YR 5/8); few, grey (reduction)
 mottles; clay; firm; gradual and wavy to:
 185-225: Yellowish red (5YR 5/6); many medium, distinct,
 brown, grey (reduction?) mottles; clay; very firm; diffuse and
 wavy boundary to:
 225-270: Reddish brown (5YR 4/4); common grey (reduction)
 mottles; few irregular shaped yellowish brown mottles; clay; very
 firm; few strongly weathered, red, yellow and white
 concretions/mineral fragments (2mm-3cm); diffuse boundary to:
 270-330: Strong brown (7.5YR 4/6); few reduction mottles (270-
 300); clay to (angular) pebbles (<2cm); poorly sorted; many
 sheared (yellow, orange, black and white) grains; diffuse
 wavy to:
 330-420: Strong brown (7.5YR 4/6); loamy clay; firm; few
 white concretions; irregular and clear boundary to:
 420-475: (water bearing layer) Yellowish brown (10YR 5/4);
 fine to very coarse sand (< 1.3cm) in clay matrix; poorly sorted;
 only weathered; weakly cemented; clear and wavy boundary to:
 475-525: Yellowish brown (10YR 5/4); few grey (reduction)
 mottles; loamy clay; firm; sesquioxides along root channels;
 wavy and wavy boundary to:
 525-560: Brown (10YR 4/3); fine sandy clay loam; weakly
 cemented; irregular and broken boundary to:
 560-580: Brown/black/yellow; fine to medium sand; very
 strongly cemented with sesquioxides; irregular and broken
 boundary to:
 580-650: Dark yellowish brown (10YR 3/4); fine to medium sand;
 yellow and cream grains; weakly cemented; along root
 channels sesquioxides; diffuse and wavy boundary to:
 650-670: Reddish gray (5YR 5/2); clay; very friable,
 isotropic; few organic material (< 5%)

Profile FS3:

a/b) 0-130: Soil
 c) 130-170: Well sorted; medium to coarse sand with few pebbles
 (<3cm); fluvial
 d/e) 170-225: Clay; fluvial;
 f) 225-270: Clay; fluvial; - gradual to:
 g) 270-330: Poorly sorted; sand to pebbles (<2cm); fluvial
 h) 330-420: Clay; fluvial;
 i) 420-475: Moderately sorted; fine to very coarse sand; fluvial
 j) 475-525: Clay; fluvial; -
 k) 525-560: Well sorted; silt to fine sand; fluvial
 l/m) 560-650: Well sorted; fine to medium sand; fluvial
 n) 650-670: Clay; contains org.mat.; fluvial;

Location of the Río Suecío Profile (FS3), part of the map 'Río Suecío'.

File Description FN4

Season : 22/7/91, middle of the rainy season
 Collector : Frank van Puitenbeek
 Location : Nequev, Rio Peje
 Coordinates : 588000/238000, Bonilla
 Elevation : road cut, 7 m. deep
 Station : 30 m.
 Slope : middle part slope of hill
 Topography : hilly
 Aspect : gently
 Vegetation : grassland
 Climate : humid tropics
 Geology : probably pleistocene pyroclastic and
 fluvial deposits
 Drainage class : well drained
 Moisture conditions soil : moist
 Depth of groundwater table : > 7m.
 Outcrops : nil
 Degree of erosion : nil
 Degree of salt or alkali : nil
 Human influence : deforestation

Characteristics: The soil is formed in partly, very coarse
 material (mudflow?) and is situated in a road cut near the river

Horizons

0-60: Dark yellowish brown (10YR 3/4); silt/clay; very friable;
 fine granular structure; diffuse and smooth boundary to:

60-115: Dark brown (7.5YR 3/4); fine to coarse sand; coated
 with orange/yellow sesquioxides; weakly cemented; diffuse and
 wavy boundary to:

115-180: Dark yellowish brown (7.5YR 3/4); fine sand; coated
 with orange/yellow sesquioxides; very strongly cemented; fine
 horizontal lamination; diffuse boundary to:

180-200: Dark brown (7.5YR 3/4); fine sand; strongly cemented
 with orange/yellow sesquioxides; common black manganese
 concretions along cracks; fine horizontal laminations; abrupt and
 wavy boundary to:

200-270: Reddish brown (5YR 4/4); silt (clay at bottom); firm;
 homogeneous; abrupt and wavy boundary to:

270-365: Yellowish brown (10YR 5/4); very poorly sorted clay
 matrix; coarse strongly weathered pebbles (< 15cm); pebbles float in
 matrix; slightly fining upward; clear and wavy boundary to:

365-390: Yellowish red (5YR 5/6) clay; firm; strong brown
 (5YR 4/6) fine sand; mixed and deformed; clear and irregular
 wavy to:

390-460: Yellowish brown (10YR 5/4); very poorly sorted,
 strongly weathered clay to pebbles (< 3cm.); few orange/yellow
 sesquioxides mottles; fining up; contains some small layers of
 sand; clear and smooth boundary to:

460-525: Yellowish brown (10YR 5/4); few orange/yellow and
 black sesquioxides mottles; fine to medium sand strongly
 cemented; few small pebble-rich (< 1.5cm) layers; abrupt and
 wavy boundary to:

525-545: Yellow (10YR 7/6) at the bottom, strong brown (7.5YR
 4/6) at the top; common white greyish reduction mottles; clay;
 friable; few concretions of orange/yellow sesquioxides; clear and
 wavy boundary to:

545-595: Strong brown (7.5YR 4/6); coarse sand in clay matrix;
 strongly weathered; partly coated with orange/yellow
 sesquioxides; weakly cemented; few black manganese concretions at
 stream channels; horizontal laminated; diffuse boundary to:

595-630: Brown (10YR 4/3); fine to medium sand; strongly
 cemented; very strongly cemented; very few lithic fragments
 (< 2cm); clear and smooth boundary to:

630-645: Brown (10YR 5/3); fine sand to pebbles (< 3cm,
 rounded, strongly weathered); poorly sorted; strongly cemented;
 clear and wavy boundary to:

645-670: Dark yellowish brown (10YR 4/4); clayish medium sand;
 strongly weathered; strongly cemented; few large, soft, spherical,
 black manganese concretions.

Profile FN4:

- a) 0-60: Soil
- b) 60-115: Parallel lamination; well sorted; fine to
 medium/coarse sand; fluvial
- c/d) 115-200: Parallel laminated; well sorted fine sand; fluvial
- e) 200-270: Clay to silt; fluvial/pyroclastic (?)
- f) 270-365: Weakly fining upward; very poorly sorted; clay to
 pebbles (< 15cm); fluvial; outer part of mudflow
- g) 365-390: Clay and fine sand; fluvial; deformed by mudflow
- h) 390-460: Fining upward; poorly sorted; clay to pebbles (< 3cm)
 fluvial; outer part of a mudflow
- i) 460-525: Well sorted; fine to medium sand; contains few grain
 lenses; fluvial
- j) 525-545: Clay; fluvial;
- k) 545-595: Parallel laminated; moderately sorted; medium to
 coarse sand; fluvial
- l) 595-630: Moderately sorted; fine to medium sand; fluvial
- m) 630-645: Poorly sorted; sand to pebbles (< 3cm); fluvial
 stream bedding
- n) 645-670: Well sorted; medium sand; fluvial

APPENDIX 3

Soil analysis:

Of each profile a mixed soil sample was taken at 25-50 cm depth:

| | Ca Meq/100g | Mg Meq/100g | K Meq/100g | Na ? | O.M. Wgt. % |
|-----|----------------|----------------|---------------|---------|----------------|
| FF1 | 1.9 | 5.0 | 0.3 | 48 | 0.3 |
| FF2 | 2.3 | 5.1 | 0.2 | 29 | 0.2 |
| FS3 | 1.9 | 5.2 | 0.1 | 41 | 0.2 |
| FN4 | 0.6 | 2.0 | 0.1 | 35 | 0.2 |

tabel: Soil analysis, FF1= Río Frío Uno Profile, FF2= Río Frío Dos Profile, FS3= Río Sucio Profile, FN4= Neguev Profile. O.M.= Organic matter.

Location of the Neguev Profile (FN4), part of the map 'Bonilla'.
