

# NUTRIENT BALANCE STUDIES TO DETERMINE THE SUSTAINABILITY OF MANAGEMENT SYSTEMS OF NATURAL AND PLANTATION FORESTS IN COSTA RICA

LUFER 18 5

R.L.H. Poels

**April 1994** 

CENTRO AGRONOMICO TROPICAL DE INVESTIGACION Y ENSEÑANZA - CATIE

AGRICULTURAL UNIVERSITY WAGENINGEN - AUW

MINISTERIO DE AGRICULTURA Y GANADERIA DE COSTA RICA - MAG

The Atlantic Zone Programme (CATIE-AUW-MAG) is the result of an agreement for technical cooperation between the Centro Agronómico Tropical de Investigación y Enseñanza (CATIE), the Agricultural University Wageningen (AUW). The Netherlands and the Ministerio de Agricultura y Ganadería (MAG) of Costa Rica. The Programme, that was started in April 1986, has a long-term objective multidisciplinary research aimed at rational use of the natural resources in the Atlantic Zone of Costa Rica with emphasis on the small landowner.

#### PREFACE

# General description of the research programme on sustainable Landuse.

The research programme is based on the document "elaboration of the VF research programme in Costa Rica" prepared by the Working Group Costa Rica (WCR) in 1990. The document can be summarized as follows:

To develop a methodology to analyze ecologicaly sustainable and economically feasible land use, three hierarchical levels of analysis can be distinguished.

- 1. The Land Use System (LUS) analyses the relations between soil type and crops as well as technology and yield.
- 2. The Farm System (FS) analyses the decisions made at the farm household regarding the generation of income and on farm activities.
- 3. The Regional System (RS) analyses the agroecological and socio-economic boundary conditions and the incentives presented by development oriented activities.

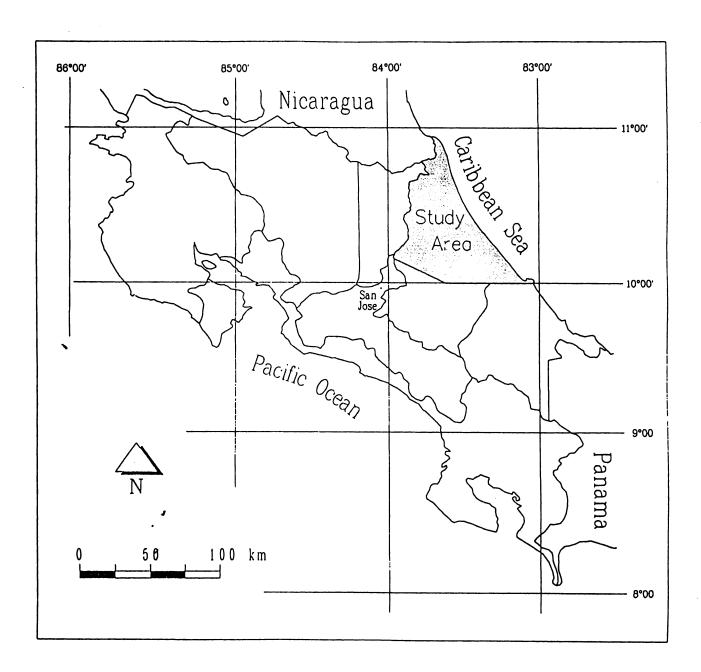

Ecological aspects of the analysis comprise comparison of the effects of different crops and production techniques on the soil as ecological resource. For this comparision the chemical and physical qualities of the soil are examined as well as the polution by agrochemicals. Evaluation of the groundwater condition is included in the ecological approach. Criterions for sustainability have a relative character. The question of what is in time a more sustainable land use will be answered on the three different levels for three major soil groups and nine important land use types.

#### Combinations of crops and soils

	Maiz, Yuca	Platano	Piña	Palmito	Pasto	Forestal I II III
Soil I	x x	x		×	x	x
Soil II	•				x	×
Soil III	×	•	×	x	x	x

As landuse is realized in the socio-economic context of the farm or region, feasibility criterions at corresponding levels are to be taken in consideration. MGP models on farm scale and regional scale are developed to evaluate the different ecological criterions in economical terms or visa-versa.

Different scenarios will be tested in close cooperation with the counter parts.

#### **ABSTRACT**

Nutrient balance studies were performed for sites in the Atlantic Zone in Costa Rica with natural and plantation forests in use for wood production. Goal of the investigations was to determine the capacities of three soil types to produce timber in managed natural forests and in plantations and to determine the sustainability of these land uses from a nutrient point of view. To this end collected data on soil, climate, vegetation and hydrology were used in dynamic simulation of forest growth using the growth model for tropical forests TROPFOR. In the nutrient balances studies attention was given, next to nutrient cycling in the soil-vegetation system to inputs by atmospheric deposition and mineral weathering and to exports of nutrients with drainage water and solids.

In the simulations, the natural forests were managed and harvested in a polycyclic system with selective harvests every 24 years according the the CELOS Silvicultural System. The plantations were harvested in three thinnings in the years 8, 12 and 16 followed by clear felling in the year 24.

It was found that managed natural forest can give a sustainable yield on all three soil types. Stemwood harvests between 25 and 50 m³/ha are possible, depending on stocking with valuable species. Plantation forest with a species such as teak (Tectona grandis) is not possible on soil type II, the poorly drained soil. On soil type III, the well drained soil of low fertility, teak can be grown but large nutrient shortages will occur, because of immobilization in increasing amounts of phytomass, especially when starting on a site with little phytomass such as agricultural land or grassland. A main problem is also the strong variation of nutrients in the soil, years with surpluses alternating with years of shortages. To avoid losses, high nutrient buffering capacities of the soils are necessary.

Calculated production levels of teak are 290 m<sup>3</sup>/ha of stemwood, including thinnings, during a cycle of 24 years. To make this land use sustainable, large fertilizer additions are necessary on soil type III. On soil type I, the well drained soil of high fertility, mineral weathering is expected to be able to supply most of the nutrients, but further research is necessary.

#### 1. Introduction

In the joint research programme of CATIE, the Ministery of Agriculture and Animal Husbandry of Costa Rica (MAG) and the Agricultural University of Wageningen, The Netherlands, executed in the Atlantic Zone of Costa Rica, the Land Utilization Types (LUT's) Bosque Natural (natural forest) and Plantationes (forest plantations) are studied, next to several agricultural LUT's. The forests in these LUT's are production forests, so natural forests in National Parks and Nature Reserves are not included. The forests in the LUT Bosque Natural (Natural Forests) produce hardwood by selective felling in a polycyclic production system, while the plantations are harvested in a monocyclic system (clear-cut and replanting).

A main objective of the research programme is to compare different land use scenarios, using linear programming. A good physical description of the different Land Utilization Types (LUT's) is necessary as a basis for calculations in which socio-economic, sustainability and political aspects are included.

Questions to be answered for the forestry LUT's are: What are the physical yields under different management systems and on different soils and how are the nutrient flows for each LUT.

In this study a simulation of forest growth and nutrient cycling will be performed for representative natural and plantation forests.

#### 2. Soils

In the Atlantic Zone Programme 3 typical soil types are discerned. They are:

I	well drained fertile soil	(Los Diamantes)
II	poorly drained soil (generally of high fertility)	(Santa Clara)
Ш	well drained soil of low fertility	(Silencio, Neguev, Cocori)

This classification is in fact a grouping of soil suitabilities, not of taxonomic groups. These 3 soil types are broad groups of soil, resulting from combining numerous soil series that have been described in soil reports by the CATIE/AUW/MAG project and by others. For each of the 3 soil types a representative set of soil properties is given in Tables 1 and 2 (Stoorvogel, pers. comm.). A representative for group I is soil series Los Diamantes (Eutric Hapludand), for soil type 2 Santa Clara (Andic Aquic Eutropept) and for soil type III Silencio (Andic Oxic Humitropept).

Table 1. A	verage soil	properties of 3	soil group	s Atlantic Zone

	Sand	silt	clay			P Olsen			pH H₂O	
I	40	40	20	0.93	0.72	16	10	28	6.0	
II	30	40	30	0.95	0.68	13	10	31	6.1	i
III	20	15	65	1.01	0.63	8	4	24	4.7	Low Festility

Table 2. Van Genuchten parameters for 2 soil groups Atlantic Zone

Soil	I		I		III	1	III	
depth	h 0-10 cm		30-40		0-10 cm		30-40 cm	
	a	b	a	b	a	b	a	b
α	0.0277	0.028	0.0701	0.0449	0.0404	0.0809	0.0187	0.0197
n	1.224	1.1791	1.2091	1.2252	1.191	1.3087	1.2666	1.2535
Θ(r)	0.001	0.001	0.189	0.202	0.0177	0.2142	0.1649	0.2225
Ksat	20	14	12.4	12.4	12.197	17.39	22.16	22.16
τ	20.43	18.683	0.0001	0.0001	15.260	4.9111	19.452	19.452

 $\Theta$  - h relations (pF-curves) and K - h relations (conductivities as function of soil suction) were calculated from these Van Genuchten parameters using the following equations:

K(h) = Ksat \* 
$$\frac{(((1+(\alpha^*h)^*)^*)-(\alpha^*h)^{*-1})^2}{(1+(\alpha^*h)^*)^{(m^*(r+2))}}$$

$$\Theta(h) = \Theta r + \frac{(\Theta s - \Theta r)}{(1 + (\alpha^*h)^n)^n}$$

$$\mathbf{m} = (1 - \frac{1}{-})$$

These calculated pF and K-h values were averaged given the following representative values for use in the simulation programme (Table 3).

Table 3. Moisture contents and hydraulic conductivities at different soil suctions of 3 representative soil types

Soil suction			content (	(% vol)	Conductiv S

16000	4.2	0.26	0.25	0.26	3*10-7	3*10-7	8*10-13

Table 3 clearly shows the differences between soil I and II at one hand and soil III at the other. Soils I and II are young Holocene soils of high fertility developed in alluvial sandy volcanic material. Soil III has the same origin but, being of Pleitocene age, has been subject to weathering for longer periods, occurring in higher positions on sloping terrain. Soil texture has become clayey by this weathering, porosity has decreased, but is still high and water contents at low suctions are lower than for I and II, reaching the same values near wilting point.

Soil III has a more developed structure than I and II, granular elements predominating. Because of this, saturated hydraulic conductivity and conductivities at low tensions are very high, surpassing those of the more sandy soil types I and II. At higher tensions, however, conductivities decrease faster because of the clayey tecture, reaching much lower levels than in the other 2 soil types. Fig. 1 shows the 3 pF-curves and Fig. 2 the two conductivity curves; conductivity of soil II is considered to be equal to that of soil I. The graphs are very regular because of their construction from the Van Genuchten parameters.

All these data have been introduced into the simulation model for forest growth TROPFOR, making it possible to simulate forest growth on 3 different soil types.

#### 3. Climate

Climatic data are available for 7 meteo stations in the Atlantic Zone: Carmen (1973-1991), Cobal (1970-1976), Los Diamantes (1971-1991), Limon (1970-1990), Lola (1970-1990),

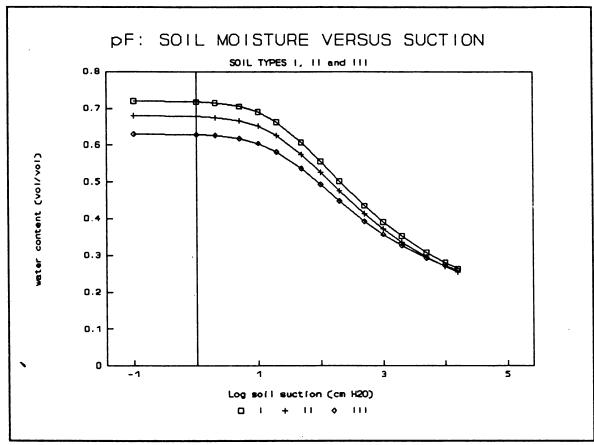

Figure 1. Θ-h relationships for three standard soil groups

Mola (1980-1991) and Rio Frio (1982-1991). These data have kindly been provided by the Instituto Meteorologico Nacional de Costa Rica and collected by D. Jansen (pers. comin).

The collected data are very divers. Sometimes only temperature or rainfall are given. Only a small part of the data is complete and then the following daily data are available: rainfall (min), maximum and minimum temperature, short wave radiation (cal/cm².d or kJ/m².d), vapour pressure at 7, 13 and 18 hours in mbar, average wind speed in km/h and the number of sunshine hours.

The best data are available for meteo station Los Diamantes at Guapiles and it was decided to prepare a climate input file for TROPFOR using 5 years with good data in which both dry and wet years occur. The chosen period is 1982 - 1986. For this period temperature, vapour pressure and rainfall data are practically complete, daily sunshine hours are available for most of the period, but part of the short wave radiation and most of the wind data are lacking.

TROPFOR needs daily data of short wave radiation, maximum and minimum temperature, avarage vapour pressure and average wind speed, so part of the short wave radiation and most of the wind data had to be constructed.

For the calculation of the short wave radiation the Angstrom equation has been used. This equation calculates the short wave radiation from the number of sunshine hours per day, taking into account daylength, extra terrestrial radiation and local radiation conditions expressed in two variables A and B. The equation is as follows:

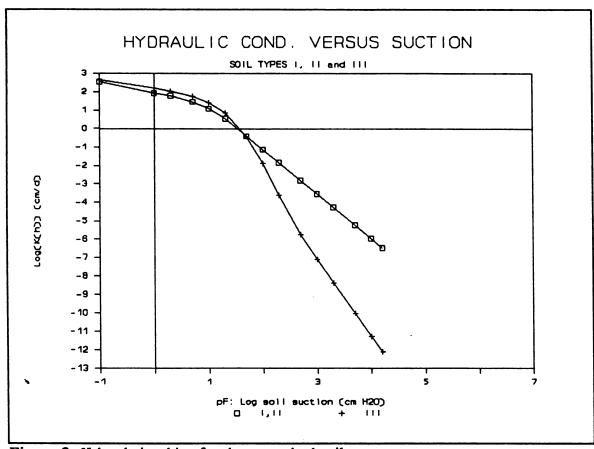

Figure 2. K-h relationships for three standard soil groups

$$Ri = Ra * (A + B*(n/N))$$

in which:

Ri = incoming short wave radiation (MJ/m<sup>2</sup>.d)

Ra = extraterrestrial short wave radiation (MJ/m<sup>2</sup>.d) or Angot-value

n = number of sunshine hours per day

N = maximum number of sunshine hours per day (daylength)

A and B are location specific constants

A and B can be calculated for a certain location when both sunshine hours and directly measured short wave radiation data are available. A and B values have been calculated for many locations. Van Keulen and Wolf (1986) give A and B values for many stations, for locations in dry tropical areas they generally give 0.25 and 0.45 for A and B respectively, for wet tropical areas generally 0.29 and 0.42. Poels (1987) used 0.28 and 0.42 for Suriname, determined by Lenselink and Van der Weerd (1973). For the Costa Rican situation A and B could be different, rainfall and humidity being very high here compared to most wet tropical stations.

To determine the A and B values for Los Diamantes, all days with both measured short wave radiation and sunshine hours were singled out and a regression was performed between Ri/Ra and n/N to determine A and B. The result is shown in Fig. 3. A was found to be 0.24

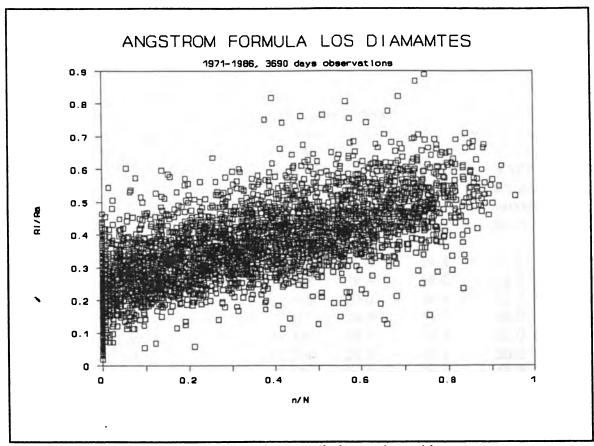

Figure 3. Relationship between short wave radiation and sunshine

and B 0.37 by a  $\dot{R}^2$  of 0.51 and 3690 observations. Hengsdijk (in press) did the same excercise for the nearby station of Copal. He found also an A value of 0.24, a B-value of 0.38 and a  $R^2$  of 0.65 by 1382 observations.

It appears, therefore, that radiation levels here are relatively low, A and B being lower than for many other wet tropical regions.

Using the values 0.24 and 0.37 for A and B, missing values for short wave radiation were calculated for Diamantes for the years 1982 - 1986.

Wind data are very scarce in the Atlantic Zone. For Diamantes they exist only for part of the year 1986. For Copal, wind data are available for 1974-1976 and part of 1973. Wind speed is generally low and rather constant at around 1 m/s. To find systematic seasonal differences in wind speed, the data for Cobal were averaged per date to give an average wind year, which was considered to apply also for the nearby station of Los Diamantes.

The climate input file CLMDAYCR.DAT was constructed as input file for TROPFOR as follows: Daily data of Los Diamantes for 1982 - 1986 were taken. Short wave radiation was taken directly from measured values or calculated from sunshine hours with the Anstrom equation using 0.24 and 0.37 for A and B. For days with both sunshine hours and direct

radiation measurement the average of the measured and the calculated value of the radiation was taken.

Vapour pressure for the model was the average of the 3 measured values at 7, 13 and 18 hours. Rainfall data were taken directly from the source files and for wind data the averages of Cobal were used, which were averaged again with the Los Diamantes data for the days for which these data existed. For illustration, part of the resulting CLMDAYCR.DAT file is given below in Table 4.

Table 4. Fragment of the input file for daily climatic data

<sup>\*)</sup> No of lines in file

DAY: Julian day RAIN: rainfall

AVRAD: short wave radiation TMAX: maximum temperature TMIN: minimum temperature

VAPP: actual average vapour pressure

WIND: average windspeed

Yearly totals and averages of the CLMDAYCR.DAT file are given in Table 5. The years 1982 and 1983 are wet and 1985 and 1986 relatively dry. The average radiation level of 13 MJ/m<sup>2</sup>.d is low compared to that of Suriname (18.7 MJ/m<sup>2</sup>.d) and also temperatures are lower.

Table 5. Average yearly climatic data of Los Diamantes, Costa Rica for 1982-1986

YEAR	RAIN mm/d	AVRAD MJ/m².d	TMAX ℃	TMIN ℃	VAPP mbar	WIND m/s
1982	4438	13.7	28.8	20.1	19.7	0.92
1983	4301	12.7	29.1	20.8	27.1	0.92
1984	4038	10.4	28.4	19.8	25.6	0.92
1985	3436	14.4	28.2	19.6	25.3	0.92
1986	3920	13.6	28.0	19.9	25.9	0.97
Average	4035	13.0	28.5	20.0	24.7	0.93
Aver. Surin.	2150	18.7	31.8	22.4	27.7	1.2

Vapour pressure data for 1982 are much lower than for the other years. This could be a systematic error. Therefore, for detailed work the year 1983 is chosen as representative for a wet year and not 1982. The year 1985 is chosen to represent a relatively dry year. A complete listing of the daily climatic data file is too lengthy to be presented here, but to give an idea of the variation during the years, the average data for all months are given in Appendix I.1. From this listing it appears that during all these 5 years no really dry period occurred. The lowest monthly rainfall was 52 mm in February 1986, but this month was preceeded and followed by months with more than 300 mm rainfall.

## 4. Vegetation

#### 4.1. Tropical lowland rain forest

Vegetation characteristics of tropical lowland rain forest for use in TROPFOR are stored in the vegetation input file. Information on biomass and growth for this forest type is scarce. The following procedure is, therefore, adopted. The forest of Kabo Suriname is used as a base, adapted and changed in so far data for the Atlantic forests of Costa Rica are available.

Changes made mainly concern the differences in soil fertility, resulting in higher nutrient concentrations in the vegetation in La Selva and a relatively lower root biomass, and the wetter climate and more clayey soil (Soil III) in the Atlantic Zone resulting in a shallower rooting depth. The higher nutrient levels in the leaves result in higher maintenance respiration rates which influence the net production. The maintenance respiration rate for leaves was calculated with the equation of de Wit et al. (1978) in Mohren (1987):

$$MRR = 0.04 * protein + 0.08 * minerals$$

Average N-content of the leaves in Suriname is 1.33 % and in La Selva 1.5 % (Osinga, in press) resulting in protein levels of 8.25 and 9.3 % respectively. Assuming the mineral content of the leaves in La Selva to be equal to that in Suriname (4 %) the maintenance respiration rates of the leaves become 0.065 for the Surinam and 0.069 per day for the Costa Rican forest, meaning that 1 ton of leaves (dry weight) looses per day 69 kg to respiration. Maintenance respiration rates for roots have also been increased from 0.015 to 0.025 and that for the sapwood of branches and stems was kept at 0.0004 (no better data being available).

Also death rates are influenced by soil fertility. Generally death rates increase at higher fertility levels. Osinga (in press) found from literature (not specified) higher death rates than those of the Kabo forest. These have been introduced in the vegetation file for La Selva (Appendix I.3).

Phytomass amounts of the undisturbed forest had to be estimated as no complete data were available. Existing data are often limited to stemwood above a certain diameter and sometimes only stemwood of valuable species. On top of that, stem volumes are estimated lower than they are because of expected losses to occur during extraction and processing of the wood. Some data are given below. Kapp et al. (1992) give 128 m³ commercial volume (DAB > 50 cm) stemwood in swampy forest; Schinkel (pers. comm.) gave data of basal areas of dry land and swamp forest near Rio Jimenez. Total basal areas of all trees with a DAB (diameter at breast height) above 10 cm was 28.4 and 21.4 m² per ha for dry land and swamp forest respectively. Other unpublished data given by Schinkel are 115 m³ of stemwood in dry land forest in Cocori with a diameter of more than 40 cm. The total amount of stemwood, including ends and stumps, badly formed and defective stems and stems with small diameters may be two to three times this amount. Assuming a average dry wood density of 0.6 (Alfaro, 1993) the weights can be calculated.

From these scattered data it is estimated for the time being until better data come available that in undisturbed dry land forest the maximum stemwood amount is about 200 t/ha. From this, the other phytomass amounts are estimated (Table 6), using ratios from the Kabo forest of Suriname (Poels, 1987).

Table 6. Estimated maximum phytomass amounts of typical undisturbed dry land forest in the Atlantic Zone of Costa Rica (t/ha)

	Living	Heartwood	Total
Leaf	15	•	15
Branch	35	55	90
Stem	70	150	220
Root	30	50	80
Total	150	255	405

Net assimilate production is divided over the plant components leaf, branch, stem, flower/seeds and roots, increasing their weight. At the same time weights decrease as living parts die to become litter.

Litter production proceeds as follows. There is a basic death rate with which living phytomass dies every day. For leaves accelerated death rates apply when there is drought stress, when the leaf area index (LAI) becomes too high and when leaves surpass there maximum age. All dead leaves go to the leaf litter compartment. For stems, branches and roots there are two dead compartments each: the heartwood and the litter compartment. Heartwood is the dead wood in living trees and wood litter is the remaining dead wood consisting of dead trees, whether still standing or lying and woody litter on and in the soil.

For these woody compartments, there is a basic death rate that tranforms living wood partly into heartwood and partly into litter. This death rate increases when maximum live weights (climax situation) have been reached. There are also maximum weights of heartwood. When these have been reached, increased rates of heartwood move to the woody litter compartments.

#### 4.2. Teak

In the lower part of Appendix I.3 the vegetation parameters for teak grown in plantations are given. Important differences with the natural forest are development rates, initial weight and fractioning of assimilates over plant organs. Further adjustments can be made when more data become available.

# 5. Simulation of undisturbed forest

Growth of the undisturbed forest was simulated using the climatic data of Los Diamantes for a period of 8 years.

At the beginning of the simulation living phytomass was set at 147 t/ha and dead heartwood amounts at 255 t/ha dry weights (Table 7).

Table 7. Phytomass amounts at the beginning and at the end of the simulation

	Leaf	branch	stem	root	flowers seeds	total
Before:						
Living	11.0	35.0	70.0	30.0	1.0	147.0
Heartwood	-	55.0	150.0	50.0	-	255.0
Litter	-	-	-	-	-	-
	11.0	90.0	220.0	80.0	1.0	402.0
After:						
Living	11.2	34.9	69.5	29.9	1.2	146.7
Heartwood	-	54.8	149.1	49.6	-	253.5
Litter	79.6	42.4	83.5	58.6	1.9	266.0
	90.8	132.1	302.1	138.1	3.1	666.2

Gross'assimilation during the 8 years was 891 t/ha, maintenance respiration 524 t/ha and conversion losses 103 t/ha, leaving 264 t/ha for dry matter increase or 33 t/ha.y. This dry matter passes through the living biomass, partly also through the heartwood phase, ending up as litter.

No data are available on the nutrient content of freshly fallen litter in Costa Rica forests. These data are difficult to acquire, as concentrations of freshly fallen litter differ from those of the litter pool and also from the composition of the plant components. The reason is that nutrients are withdrawn from e.g. leaves and twigs before they drop, and that during decomposition on the forest floor concentrations change by oxidation of organic C and preferential withdrawals. In our calculation, the composition of freshly fallen litter is set equal to the composition of the plant components, as withdrawal does not change the amount of nutrients that becomes available to the vegetation. The difference is that the nutrients that are withdrawn from the litter before the drop become available faster to the vegetation than when they go through decomposition on the forest floor and also that they do not run the risk of being leached after liberation and before uptake. Table 8 gives the concentrations of the Kabo forest in Suriname, taken from Poels and Bijker, in press, adapted for the Costa Rican situation where possible.

Table 8. Provisional concentrations (%) of plant components (a) and litter pools (b)

# 6. Simulation of natural forest under polycyclic management

The following situation will be simulated. Un undisturbed forest is being logged for the first time. A light exploitation is carried out and care is taken to limit logging and extraction damage as much as possible by using inventory maps, planning extraction roads, employing direction felling and winching where possible and useful. For damage controlled exploitation methods, see Hendrison, 1990.

During the exploitation 25 m³/ha of stemwood is extracted (15 t) by which a total phytomass of 54 t/ha is killed. The exploitation is followed by a refinement. This is a treatment to increase the growth of small and medium sized valuable trees for future harvests by killing large trees of non-valuable species and defective trees of valuable species. Trees are not felled in refinement but killed while standing by girdling, with or without the use of herbicides. By such treatment growth of valuable trees may increase tenfold by the combined effect of improved light conditions and nutrient liberation from additional decomposing litter. In the simulated situation it is assumed that the refinement kills 40 % of the remaining phytomass (Table 10).

Table 10. Phytomass changes during exploitation and refinement

	Leaf	branch	stem	root	flowers seeds	total
Before:

Heartwood	-	19	55	18	-	92
•						
TOTAL:	4	30	80	28	0.3	142.3
After treatment:						
Living	5	17 -	36	17	0.5	75.5
Heartwood	-	26	78	26	-	130
TOTAL:	5	43	114	43	0.5	205.5

The situation after treatment is the starting point for the simulation of forest growth. Forest characteristics as given in Appendix I.3 (upper part) were introduced and the soil characteristics from Appendix I.2 (Costa Rica III, unfertile, well drained). This forest on this soil was subjected to the daily climatic data from Los Diamantes (Table 4). Growth was driven by solar radiation and the watersupply was calculated from the water balance. Table 11 gives the course of the phytomass build up during the years for 2 situations: without further interference and with a second refinement after 10 years. During the refinement in year 10 the biomass killed was as follows (t/ha): leaf 3.02, branch 43.44, stem 84.40, root 35.38 and flowers/seeds 0.57.

Table 11. Development of phytomass (t/ha) in treated natural forest without (a) and with (b) second refinement at year 10

	Leai	•	bran	ch	stem		root		flow seed		total	
Year	a	b	a	b	a	b	a	b	a	b	a	b
-1	11		90		220		80		1.2		402

10	8	5	86	43	198	114	78	43	1.1	0.5	372	206
11	12	12	90	51	207	129	80	50	1.1	0.7	390	242
15	8	10	89	69	219	165	79	69	1.1	1.0	397	314
20	12	8	90	86	218	198	80	78	1.2	1.1	401	372
24 `	12	12	90	90	218	220	80	79	1.2	1.1	401	402

It appears from Table 11 that a second refinement at year 10 is advisable when a large part of the phytomass consists of trees of non-valuable species or of low quality stems of valuable species (hollow, rotten, badly formed). At year 24 the difference in phytomass between both treatments has disappeared. Average stem size is higher in case a and there may be differences in exploitable stem volume. Regular refinements that keep the phytomass considerably below the maximum (climax) weights result in lower maintenance respiration and death rates. A negative aspects of these refinements is the irregular addition of litter to the forest floor causing irregular nutrient supply from decomposing organic matter and danger of nutrient leaching.

It is clear from Tables 10 and 11 that an extraction of 15 t/ha of stemwood once every 24 years is very modest and far below the production capacity of the forest. Only 6 % of the organic matter production is extracted, the remainder being available as litter to support the natural functions of the forest.

## 7. Simulation of the growth of forest plantations

Important differences between natural forest and forest plantations are age distribution and phytomass fluctuations combined with differences in nutrient supply from decomposing litter and variations in nutrient uptake.

The crop growth model does not take into account differences in botanical composition, but variations in assimilation speed, in maintenance respiration and death rates, and in assimilate distribution can be brought into the model.

Below, the result of a simulation of a teak plantation is given with planting of 1600 trees at the end of year 0, thinnings in the years 8, 12 and 16 and harvest in year 24. It should be stressed that results are very provisional, as nearly no growth data of teak were available, so calibration of the model was not possible. As soon as data become available, simulations may be improved. Table 12 gives the development of the phytomass.

Table 12. Development of phytomass (t/ha) in a forest plantation

a: situation at end of the year

b: directly after thinning

#### 8. Yields

The natural forest produces every 24 year 25 m³ or 15 t/ha of high quality hardwood of large dimensions. Higher yields are possible when the natural forest contains a high percentage of marketable species as is the case in many Costa Rican forest such as those dominated by Carapa guianensis. In those cases harvests can be larger and refinements accordingly smaller. Therefore 2 yield levels natural forest are considered: 25 and 50 m³/ha every 24 years. This is the net production which is exported from the forest.

The forest plantation produces every 24 years stemwood from 3 thinnings and from one final cut. Planting is done in former natural forest land, now under grassland. Plant density is 1600 trees/ha. Between year 1 and 8, this number decreases to 800 by natural mortality and thinnings without harvest. The three thinnings that are harvested are in the years 8, 12 and 16. Only stemwood is harvested and of the stemwood one third stays behind in the forest as stumps, upper part near branches and defected stems. Details of the exploitation are given in Table 13. It is assumed that the average length of the exported stems is 10 m, that the form factor is 0.7 and that the wood density is 0.6. The form factor (ff) gives the deviation between the average stem form and a cylinder as follows:

Stem volume = basal area \* lenght \* ff

Table	13.	<b>Exploitation</b>	scheme	of the	forest	plantation
-------	-----	---------------------	--------	--------	--------	------------

		Stemwoo	d (t/ha)	number of	volume per	diameter of stems	
Year	treatment	killed	exported	stems	stem (m)	(cm)	
8 、	thinning	18.85	12.57	185	0.113	14	
12	thinning	33.74	22.49	178	0.211	20	
16	thinning	58.65	39.10	170	0.383	26	
24	final cut	149.71	99.81	157	1.060	44	
Total		260.95	173.97	690			

The number of stems of the thinnings and of the final cut is smaller than 200 because of the naturally occurring mortality of 1 % per year.

Average stem diameters of 44 cm are a bit small for a final cut. Planters like Huizinga (1993) claim a faster growth: 1.3 to 1.6 m³ per tree at year 20 at the same tree density. This would mean that the stems (lenght (10 m) and form factor (0.7) being the same) have diameters of 49 to 54 cm. More growth data are needed, and especially over prolonged periods, as very fast initial growth is often followed by slower growth or even stagnation in later stages. Very optimistic prognoses often result from extrapolation of favourable growth during the first years.

#### 9. Nutrients

The question is: do nutrient shortages occur in the short run (during the growth) or in the long run (after several exploitation cycles). This problem is rather complex. Nutrients come available to the vegetation from different sources: atmospheric deposition (wet and dry), biological Nitrogen fixation, weathering of minerals, decomposition of organic matter and runon of water and sediment. On the other hand there are losses: leaching, runoff and erosion, and export by harvest.

Atmospheric inputs and weathering inputs of elements are relatively small. It is assumed that these inputs are constant and equal for both vegetations. Amounts have been estimated (Table 14) using data from Poels (in press 2). Weathering inputs are for the Costa Rican well drained soils of low fertility. For the soils of high fertility the inputs are estimated to be threefold.

Table 14. Estimated yearly inputs of nutrients by the atmosphere and by mineral weathering

Element	N	P	K	Ca	Mg
Atmosphere Weathering Total	5 0 5	0.1 0.2 0.3	1 7 8	1 7 8	3 3 6
********************					

Decomposition of organic matter contributes the largest quantity of nutrients to the vegetation in a forest situation. The nutrients do not come available at the moment of litter fall but later, depending on the type of litter. The following decomposition times will be used: leaf 0.5, small woody litter 2 and coarse woody litter 5 years. Decay rates are therefore 2, 0.5 and 0.2 per year. To simplify the calculation, it is assumed that all fine woody litter is completely decomposed after 3 years and coarse woody litter after 10 years (Table 15). Given is the percentage of the litter that falls in year 0 that decomposes in a certain year, liberating the nutrients contained in the decomposed part.

Table 15. Decomposition (%) of different litter types with time

Year	0	1	2	3	4	5	6	7	8	9	10
Leaf Fine woody Coarse woody	50 10 0	50	25 17	14	12		_	_	5		3

Fine woody litter are twigs, branches, roots and seeds with diameters less than 3 cm. Coarse woody litter are stems, roots and branches thicker than 3 cm. To translate litter into these categories half of the root and branch litter and all of the flower/seed litter is considered to be fine woody litter and half of root and branch litter and all of the stem litter to be coarse woody litter.

#### 9.1. Climax situation natural forest

This situation is relatively simple as the forest is in a steady state with litter decomposition speed equal to litter fall for all litter types. Yearly liberation of nutrient from decomposing litter are as given in Table 9. A summary of the nutrient flows for the climax situation is given in Table 16.

Element	N	P	K	Ca	Mg
Atmospheric input	5	0.1	1	1	3
Weathering input	260	0.2	172	104	<i>3</i>
Organic matter turnover	260	15.9	173	184	31
Export by leaching, erosion	5	0.3	8	8	6

#### 9.2. Natural forest under polycyclic management

Organic matter turnover is influenced by harvesting and silvicultural treatments. Litter fall and decomposition are no longer in a steady state. For each year nutrient flows have to be calculated separately. Appendix II.1 gives the formation and the death of organic matter components as calculated with TROPFOR.

The yearly litter production data. not including litter from treatments. Appendix II.1 are shown also in Fig. 4. After treatment in year 10, litter production drops sharply, favouring phytomass increase. After year 20, litter productions increase strongly because phytomass components are approaching

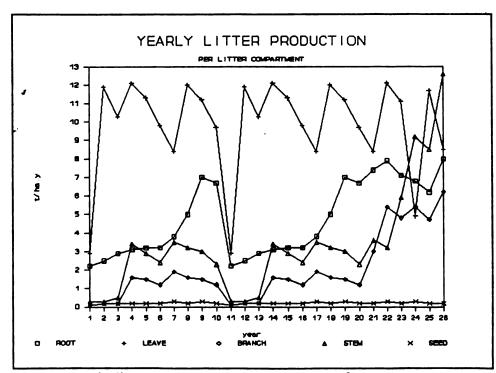

Fig. 4. Yearly litter production in treated natural forest

climax amounts. When the second harvest takes place in year 24, litter production of year 25 becomes equal to that of year 11, making new room for dry matter increases.

That a refinement near year 10 is necessary is illustrated in Figs. 5 and 6. Without refinement, stemweight increases stop at year 15, as mortality becomes more or less equal to growth. With refinement at year 10, stem weight increases can be kept high till year 22. A second harvest at year 24 is to be preferred over a harvest at year 20 to increase the size of the stems to be harvested.

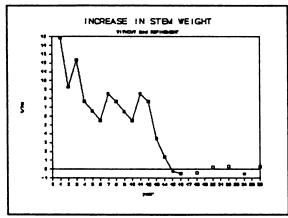

Figure 5. Increase in stem weight without refinement at year 10

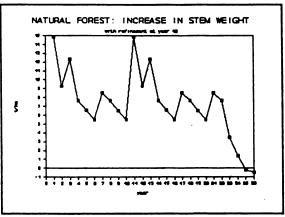

Figure 6. Increase in stem weight with refinement at year 10

Combining the data of Appendix II.1 with the concentrations of Table 8, nutrient balanses were constructed. They are given in Appendix III.1 Uptake of a nutrient was calculated straightforward by multiplying amounts of plant components formed with their concentrations. Liberation of nutrients from decomposing litter was calculated step wise. First, the litter was grouped in leaf, fine woody and coarse woody. Then, for each group per year, the amount was calculated that decomposes and these amounts were multiplied with the concentrations and added per year.

During the years preeceeding the treatment, liberation and uptake are in balance (climax situation). In year zero, harvesting and refinement takes place, producing much litter of which decompositions reaches a peak in year 1. In that year 476 kg N, 32 kg P, 323 kg K, 475 kg Ca and 60 kg Mg are liberated from decomposing organic matter. After subtraction of uptake there is a surplus of 178 kg N, 13 kg P, 123 kg K, 234 kg Ca and 24 kg Mg reaching the soil buffer.

Liberation peaks are at the years 1, 11 and 25 for all elements and liberated amounts decrease slowly till the next treatment. Uptake varies per year because of the influence of the weather, favourable years (3, 7, 13, 17 and 21) with higher insolation having more production and nutrient uptake than other years. When these favourable years are long after treatment (years 7, 17 and 21) and, therefore, at low litter levels, nutrient shortages occur that will be claimed from the soil buffer. These maximum shortages in one year are: 123 kg N, 8 kg P, 87 kg K, 125 kg Ca and 16 kg Mg/ha in year 21.

Both nutrient surpluses and shortages in the soil have negative effects. Surpluses such as in year 1 may result in increased leaching and losses from the ecosystem and shortages result

MAIBLIOTEC

in decreased growth. The quality of the soil, i.c. the buffer capacity is important in this respect. Surpluses and shortages in this managed natural forest are relatively small.

A surplus of, for instance, 123 kg K can easily be taken up by the soil, giving an average increase of K-adsorbed from 4 to 4.05 cmol/kg in the layer 0-50 cm. For a surplus of 234 kg Ca/ha, the adsorbed amount of Ca only has to increase with 0.19 cmol(+)/kg of soil. Leaching losses are considered to be very low, as are the maximum shortages in year 21.

Table 17. Summary of nutrient flows in managed natural forest (kg/ha.y)

Element	N	P	K	Ca	Mg
Atmospheric input	5	0.1	1	1	3
Weathering input	0	0.2	7	7	3
Average O.M. turnover:			•		
- release	271	17	179	194	32
- uptake	268	16	177	191	32
Export with harvest:					
- 25 m <sup>3</sup> /24 y	1.8	0.1	1.6	3.8	0.3
$-50 \text{ m}^3/24 \text{ y}$	3.6	0.2	3.1	7.6	0.6
Maximum yearly surplus	178	13	123	234	24
Maximum yearly shortage	123	8	87	125	16
Export with leaching, erosion	5	0.3	8	8	6

# 9.3. Plantation forest of teak

Simulated organic matter flows in a teak plantation are given in Appendix II.2. Compared with the organic matter flows under managed forest amounts are lower and variation larger. There are more treatments and there is more extraction of wood. The results of these treatments (three thinnings and one final cut) are presented in the second line of the years 8, 12, 16 and 24.

The yearly litter production for each compartment (not including litter from treatments) is given in Fig. 7. Leaf litter production is at about the same level as in natural forest, strongly influenced by thinning, but not as strong as shown in the figure, where the sharp peaks are caused by imperfect simulation. The peak leaf litter levels of the years 10, 14, 18, 22 and 34 should be leveled of with the preceding years. Litter production of roots, stems and branches is smaller than in natural forest because of low phytomass levels.

Increases in stemweight (Fig. 8) are higher than in managed natural forest, mainly because of the lower phytomass and corresponding lower maintenance respiration rates and death (litter production) rates.

Nutrient balances are given in Appendix III.2. In the first year a soil input is given, calculated with the QUEFTS method (Janssen et al, 1990) to give the starting amount of nutrients for the plantation that the soil can supply. The amounts have been calculated from

soil analysis data as given in Table 1 for N, P and K. For Ca and Mg amounts have been estimated. These available soil nutrients for the first year are (kg/ha): N 72, P 6, K 102, Ca 200 and Mg 50.

During the whole growing period, large shortages (liberation uptake) occur, in sharp contrast to the managed forest (Table 18). Main cause for these shortages are the lack of phytomass at the beginning of plantation the and the fast phytomass increase during the growth.

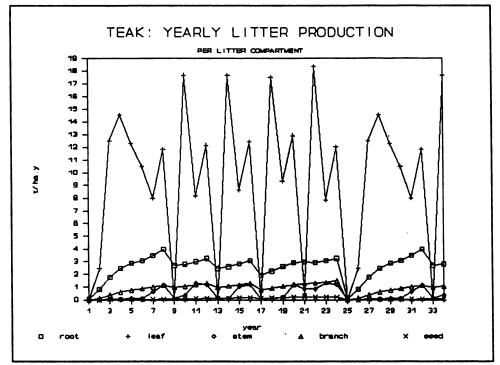

Figure 7. Yearly litter production in a teak plantation

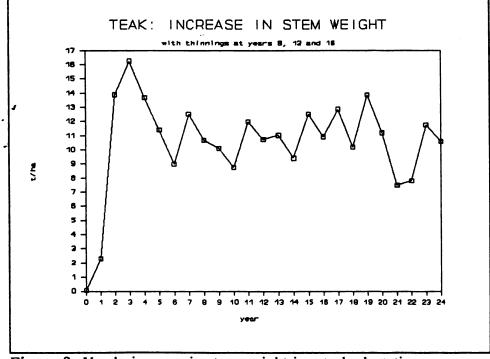

Figure 8. Yearly increase in stem weight in a teak plantation

Table 18. Maximum cumulative surpluses and shortages of nutrients (kg/ha)

	N	P	K	Ca	Mg
Managed natural forest					
Surpluses	443	32	319	614	61
Shortages	371	27	260	499	50
Teak plantation					
Surpluses	4	2	60	158	42
Shortages	1546	102	1028	1872	166

In managed natural forests, surpluses build up with some interruptions till year 12. From year 13 on, shortages start to occur that continue for most nutrients till the year 23 (see also App. III.). The surpluses are larger than the shortages that come afterwards. That means that there are always enough nutrients provided that the buffer capacity of the soil is large enough.

For teak the situation is completely different. Surpluses only occur in year 1, when the soil provides the nutrients according to QUEFTS and uptake is still small. During the whole growing period there are shortages. Maximum cumulative shortages are reached in the year 23 for all nutrients except Ca, where the maximum is reached in year 24. This is because Ca mainly occurs in the wood, that decomposes slower than leaf litter.

Table 19. Summary of nutrient flows in the teak plantation (kg/ha.y)

Element	N	P	K	Ca	Mg
Atmospheric input	5	0.1	1	1	3
Weathering input	0	0.2	7	7	3
Average O.M. turnover:					
- release	204	12	133	108	24
- uptake	267	16	175	186	31
Export with harvest	21.0	1.3	18.1	44.2	3.6
Maximum yearly surplus	33	2	60	158	42
Maximum yearly shortage	311	19	203	224	36
Export with leaching, erosion	5	0.3	8	8	6

Yearly flows are given in Table 19. Average nutrient uptakes are higher than release from organic matter decomposition for all elements, indicating the shortages in the short run. Shortages in the long run appear from the line: export with harvest. Yearly exports are much higher than in managed natural forest (Table 17) and also higher than atmospheric and weathering inputs combined.

#### 10. Discussion

Large differences exist between managed natural forest and a forest plantation, even if in both cases the cutting cycle is 24 years. In case of the natural forest, only few big stems of high quality trees are harvested, while in the case of a plantation of e.g. teak, a complete cut is executed at the end of the cycle, with all stemwood removed, including stemwood of thinnings.

The starting situation is better in managed natural forest with a high phytomass containing a large quantity of nutrients. During treatment the phytomass amount decreases somewhat, giving a surplus of nutrients. Also in the long run this land use is sustainable from a nutrient point of view, even on the well drained soils of low fertility, where the yearly input of nutrients from the atmosphere and from weathering is larger than the export of nutrients with harvested stemwood. Even a double harvesting level of 50 m3/ha per cycle (30 t of stemwood) seems possible, but in that case nutrient supply becomes more tight in the long run and concentrations of the drainage water will have to decrease somewhat.

Growing of teak or another tree species in an intensively managed plantation is a completely different matter. When starting from grassland or agricultural land, which is often the case, large nutrient shortages will develop during development of the trees because of immobilization of nutrients in phytomass. Average yearly shortages during the first cycle are: N 63, P 4, K 42, Ca 78 and Mg 7 kg/ha. During the first years these shortages are much larger (Table 19, Appendix III.2). Improvement of the nutrient situation will occur in the second cycle, because of decomposition of harvest refuse, if this litter is evenly divided over the area and not burned (Appendix III.2, nutrient balanses, years 25 -34).

Export of nutrient with harvested stemwood is much larger than in managed natural forest. In the long run, after several cycles, shortages will occur. This land use is not sustainable, from a nutrient point of view, on the well drained soils of low fertility without fertilizer addition. The average yearly export by harvested stemwood is significantly larger than the inputs by the atmosphere and by weathering. On fertile soils, that have an estimated yearly nutrient release by weathering that is at least three times that of the low fertility soils, this land use is considered sustainable, but more weathering research is necessary to make better estimates.

The yields considered here were calculated assuming no nutrient limitation. Whether limitations occur depends on the fertility and buffer capacity of the soil, on the biological nitrogen fixation and on fertilizing. Soil fertility is expressed by the initial available nutrients calculated with QUEFTS and by the yearly release from weathering. Necessary soil buffers are much larger in the teak plantation than in managed natural forest (Tables 17, 18 and 19). Maximum yearly and cumulative surpluses are limited for both forests. Not much increase in drainage water concentrations are expected. Nutrient shortages are very limited in managed natural forest, but very large in the teak plantation, especially the cumulative shortages (Table 18). The buffer capacity of the soil should be large enough to supply during the first cycle 17 mgr/kg P, 0.44 cmol(+) of K, 0.39 cmol(+) of Ca and 0.06 cmol(+) of Mg per kg of soil for the whole soil till a depth of 50 cm. For the fertile soil this seems possible, but for the low fertility soil (III, Table 1) this seems too much, especially when rooting is not very intensive throughout the whole soil depth of 50 cm. More research in the nutrient supplying capacity of the soils is needed.

#### 11. Conclusions

The land utilization type (LUT): Bosque natural is a sustainable land use from a nutrient point of view on well drained soils of low fertility in the Atlantic Zone of Costa Rica, provided that harvests are kept low and executed with care to limit harvesting damage. Additional advantages of this land use type are high ecological value and the good soil protection.

The LUT Plantaciones: the growing of teak or other tree species in plantations produces higher amounts of stemwood (Table 13), but export of nutrients with the harvested stemwood is also much larger, making the land use not sustainable from a nutrient point of view on the well drained soils of low fertility in the long run without fertilizer input. In the short run even larger nutrient shortages occur due to immobilization of nutrients in the increasing phytomass. For a good growth, supplementary fertilizing with 50 kg P, 200 kg K and 300 kg Ca per ha in the second year seems advisable for the first cycle.

Also large N-shortages occur in the teak plantation during the first years, but artificial fertilizing with N could be probled expensive. Teak itself is not able to fix atmospheric N biologically, but some N comes in with free living N-fixing bacteria, with N-fixing bacteria living in symbiosis with undergrowth species and with atmospheric deposition. Soil humus decomposition can supply part of the shortage and the remainder of the shortage will cause a temporary growth reduction.

Calculations were executed for one soil type only, Soil type III: the well drained soils of low fertility. The provisional adaptation for Soil type I (well drained fertile soil) is that nutrient release from mineral weathering is considered to be three times that of Soil type III. For the poorly drained soil (Soil type II) much more adaptations are necessary. It is well known that teak cannot grow in poorly drained soil. After artificial drainage it is possible to grow teak, but the drainage demands of teak are higher than of e.g. bananas. Artificial drainage for teak could be, therefore, probihitively expensive. Drainage research for teak is outside the scope of this study, but it can be said that with sufficient drainage yields of teak on Soil type II may approach those of Soil type I.

Natural forest on Soil type II is adapted to periods of waterlogging. Some species like Carapa guianensis are often more abundant in swamp forests than in dry land forests. However, adaptation to swampy conditions has its price. It costs additional energy to supply oxygen to the roots, reducing the growing speed. Moreover, mortality in swamps is higher as trees are more prone to windworp. To simulate forest grow in swamps much more data are necessary. At this time, it is only possible to estimate a reduction factor for the average productivity in swamps, compared to that on well drained soils. And it should be realized that all swamps are different, with different degrees of water logging and different growth reductions. Till better data become available it is estimated that the production level in swamps is 30 % lower than on well drained land with the same soil fertility.

For the linear programming of land use options in the Atlantic Zone by "Projecto de cooperacion CATIE/UAW/MAG in Guapiles to following results are presented:

Managed natural forest gives once per 24 years a yield of 25 m³ of stemwood per ha that contains 44 kg N, 2.7 kg P, 38 kg K, 92 kg Ca and 7.4 kg Mg. In well stocked forests on all three soil types a double yield of 50 t/ha is possible, when refinement treatments are reduced accordingly. No or few nutrient limitations are expected for this type of land use on good soils of soil types I, II and III with sufficient nutrient buffering capacities.

Plantations of teak are possible on soil types I and III. The calculated production level amounts to 174 t/ha or 290 m3/ha per 24 years (Table 13). The exported stemwood contains 504 kg N, 31.3 kg P, 435 kg K, 1061 kg Ca and 85 kg Mg. This is much more than the inputs by atmosphere and mineral weathering in well drained soils of low fertility. Fertilizing is needed to make this land use sustainable from a nutrient point of view, not only to compensate for nutrient export with the wood but also for the phytomass build up during the first cycle and to compensate for leaching and erosion losses that result from the strong phytomass fluctuations that are unavoidable with this type of land use. On soil type I less nutrient problems will occur. A weathering speed of 3 times that of Soil type III (Table 14) would be enough to supply the necessary K and Mg, for Ca and P still shortages would occur in the long run.

Better estimates of yields and nutrient flows can be made as soon as more data become available. The development of simulation and calculation procedures was the main goal of this study.

# **Explanation**:

MONTH 8612: December 1986

RAIN: rainfall

AVRAD: short wave radiation

TMAX: daily maximum temperature TMIN: daily minumum temperature TMPA: daily mean temperature TMPD: daytime mean temperature

SVAP1: saturated vapour pressure at daily mean temperature SVAP2: saturated vapour pressure at daytime mean temperature

SVAP3: saturated vapour pressure at minimum temperature

VAPP: actual average vapour pressure

R.H.1: average daily relative air humidity (VAPP/SVAP1) R.H.2: average daytime relative air humidity (VAPP/SVAP2)

R.H.3: relative air hymidity at minimum temperature (VAPP/SVAP3)

WIND: average daily wind speed
